Convalescence was uneventful. The patient recovered and returned to work. The digestive symptoms all disappeared. The bowels became perfectly regular. March 3, 1926, the patient's physician reported that there had been no recurrence of abdominal symptoms, and the patient was in splendid health.

Case VI.—K. M.; female; forty-six years of age; single. For eight years, at intervals of two or three weeks, the patient had acute attacks of abdominal pain. These would commence in the right upper quadrant and spread over the entire abdomen. The attacks were attended by nausea and vomiting and were so severe that the patient's physician, at times, prescribed morphine. Medical measures having been exhausted, operation was advised.

Laparotomy was performed March 3, 1917. On opening the abdomen it was found that there was marked enteroptosis. The stomach was well below the umbilicus—practically at the crest of the ileum. The great omentum was adherent over the descending colon from almost the true pelvis upward to the splenic flexure. This was detached. There was complete rotation of the cecum—the butt end rotated from above downward and from without inward. There was a large diverticulum of the ascending colon, with bands across angulating and obstructing it. These bands were bisected longitudinally. The appendix was removed; the ascending colon and cecum plicated and anchored in the right flank.

Convalescence was uneventful and the patient rapidly recovered. The attacks of nausea and vomiting disappeared, and in the nine years since the operation there has been no recurrence of the epigastric pain, or of the other gastrointestinal symptoms.

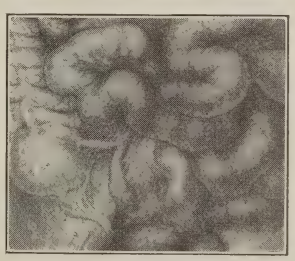

Fig. 10.—Case X. C. C. Lower part of Fig. 9.

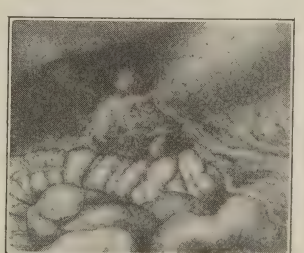

Fig. 11.—Case X. C. C. Upper part of Fig. 9.

Case VII.—M. G.; male; forty-five years of age; married. This patient was markedly constipated and had very severe attacks of epigastric pain which recurred at intervals of a few weeks. He had lost fifteen pounds in three months, and was markedly depressed. Operation was performed May, 1917. There was a very strong band from the base of the gallbladder well down towards the gastrohepatic omentum, causing the cystic duct to be kinked close to the entrance of the common bile duct. The band was attached to the duodenum just beyond the pylorus; below, towards the greater curvature of the stomach, a portion of the band found attachment on the gastrocolic omentum, and the right portion of the band went towards the hepatic flexure of the colon.

The terminal ileum was tightly adherent to the posterior abdominal wall over the brim of the pelvis; the appendix was thickened and lay toward the outer side and underhung a portion of the cecum; below was a cecal diverticulum which was prevented from increasing greatly in size by an adhesion to the brim of the pelvis which bound it tightly down. The bands were bisected; the terminal ileum freed; the appendix removed. The raw surfaces were all turned in.

The patient recovered. His symptoms completely disappeared. In one year he gained forty pounds, and five years after the operation he reported that he was in the best of health.

Case VIII.—P. Z.; female; thirty-five years of age; married. This patient consulted me November, 1908, for pain low down in the abdomen; extreme nervousness and almost constant gastrointestinal distress. Two years of careful medical treatment had caused no improvement in the patient's condition, and operative procedure was advised.

Laparotomy was performed November, 1908. The uterus, which was prolapsed, was brought into normal position by modified Gilliam method. There was a fibrocystic mass in the right ovary which was removed, except for a small piece of healthy tissue. The appendix was the seat of an old inflammation and was thickened, bound down; angulated. Three feet from the ileocecal valve was a Meckel's diverticulum which was ulcerated in two places at the extreme end of the pouch, and was full of intestinal content. This was removed, as was the appendix also. The latter appeared normal.

The patient's convalescence was uneventful. The abdominal pain completely disappeared. She gained in health and strength and for twelve years was absolutely free from symptoms. There was no gastric distress and the bowels moved freely.

In April, 1920, symptoms developed of a growth in the pelvic colon. She consulted a physician, in the Western State where she lived, who palpated a distinct mass in the left side. He performed a laparotomy, but so much pathology was found that no attempt was made to correct conditions.

August, 1920, the patient returned East for consultation. On examination I found a mass as large as a grapefruit in the left iliac region. The mass was tender and painful and not freely movable. Exploratory laparotomy was advised.

Operation was performed September 1, 1920. The omentum was found adherent to the line of the recent incision. At the central portion of the pelvic colon was a carcinomatous mass, about the size of an orange, which narrowed the gut. Sixteen inches of the colon and a wedge of the mesosigmoid were removed. The pathological report was: "Adenocarcinoma, with extensive, acute inflammation of the submucous and muscular coats."

The patient recovered from the operation and returned to her home in the West. She continued in good health for over a year, when she began to show signs of recurrence near the site of the original growth. Colostomy was refused and palliative treatment was instituted. Radium was applied, but the cancer continued to extend and the patient finally died December 5, 1921.

Case IX.—C. B.; female; forty years of age; married. February 9, 1921, this patient consulted me because of recurrent attacks of abdominal cramps and vomiting. These occurred every three or four days with intervals of six or seven days. The vomitus was mucoid at the start; later of the greenish, bilious type; the pain was at the level of the umbilicus and there was abdominal distention at such times. The patient was much emaciated. Examination showed a mass present in the left abdomen; solid; movable. Exploratory laparotomy was advised.

Operation was performed February 12, 1921. The terminal ileum for about two feet was markedly hypertrophied, being about three times normal thickness. The cecum was extremely mobile with very large diverticulations. From the point where the cecum and lower part of the ascending colon rotated downward and inward (where is commonly situated a mass of pericolic bands) was found a very dense band which held the ascending colon together against the posterolateral shelf. On the ascending colon, just where this band was tightest, was a carcinomatous stricture almost completely closing off the large bowel. The cecum was dilated with a mass of fecal matter.

The cecum, ascending colon, hepatic flexure and about one third of the transverse colon, with ten inches of terminal ileum and the appendix were exsected close to the posteroabdominal wall. The cut end of the transverse colon was inverted, with a purse string suture and interrupted Lembert stitches, and the closed end covered over with great omentum. The severed ileum was brought up into position and an end to side anastomoses performed. The meso of the terminal ileum was fastened by interrupted stitches of black linen to the transverse mesocolon so as to close off the opening.

Pathological report was "adenocarcinoma of the ascending colon."

The patient rallied well, and for two years and a half was absolutely free from symptoms. Her bowels moved daily; she gained weight and was perfectly normal in every respect.

August, 1923, she commenced to flow. The discharge was bloody and irritating and gradually increased in volume.

In February, 1924, I was again called in consultation. The patient had had two severe vaginal hemorrhages and was in a very weak condition. On examination I found a mass in the hollow of the sacrum, impinging against the cul de sac and pressing forward at the site of the junction of the vaginal mucosa and the cervix. At this site was an ulcer which ex-

tended through the vaginal wall to the space between the rectum and vagina. The cervix was bilaterally lacerated and presented on each lip an epithelioma. The deep tear in the cervix, towards the right broad ligament, was ulcerated and indurated and the cancer was evidently invading the circular artery.

The patient was in such condition that ligation of the arteries was postponed. The uterus was wiped out with iodine, and the whole ulcerated surface cauterized with Percy and electric cautery and packed with iodoform gauze.

February 15, 1924, the patient was given a blood transfusion (1000 c. c.) and was in very satisfactory condition. On February 16th laparotomy was performed. The right ovary and tube were cystic and bound down to the broad ligament and wall of the pelvis. The uterus was bound down by adhesions to the pelvic colon, and a large tubal ovarian abscess, about the size of an orange, occupied the cul de sac at the left side of the pelvis. The tube, ovary, and abscess with its containing wall, were removed. The left ureter was exposed just below the bifurcation of the left common iliac artery and the left internal iliac artery was ligated in two places, one half inch apart. The artery at the site of the ligation was crushed by a strong clamp; the identation thus formed a groove in which the ligature was placed. The right internal iliac was treated in the same manner.

The cancerous growth was extensive in the floor of the pelvis and developed widely in both broad ligaments. No cancerous disease was found in the abdomen—showing that the two conditions (abdominal and pelvic) were undoubtedly independent.

In September, 1924, the patient returned for examination. She had had no discharge and no recurrence of the hemorrhage. There had been a gain of six pounds since the operation in February. During the year, following this examination, a slight vaginal discharge developed; the patient was treated by x ray. Gradually she grew weaker and died in September, 1925, nearly five years after the removal of the large adenocarcinoma of the ascending colon, and having had no recurrence of malignancy in the upper portion of the abdominal cavity.

Case X.—C. C.; male; forty-seven years of age; married. Three years previous to consulting me this patient began to have attacks of vomiting, lasting several days. These increased in frequency, and when I saw the patient his general condition was very poor, in fact, he was practically starving to death. He complained of constipation, and pain in the epigastrium, four or five hours after eating. He had lost considerable flesh and strength. On examination I found general abdominal tenderness, more accentuated in the right lower quadrant, and much gas. There was marked gastric dilatation. Operation was advised.

On opening the abdomen, December 25, 1913, almost complete pyloric obstruction was found; a marked diverticulum of the duodenum, with a mass of inflammation about it, and adhesions between the neck of the gallbladder and duodenum. There were enlarged glands about the pylorus and back of the liver.

Posterior gastroenterostomy was performed. There was an ileal band which was cut transversely and sutured longitudinally. The appendix was normal, but was removed. There was a small fibroid of the right lobe of the liver at the free margin. This was excised and the liver sutured.

Convalescence was uneventful. The patient gained in weight until he had put on forty-five pounds, and for eight years, following the operation, was in perfect health. In October, 1921, carcinoma of the rectum developed from which he, later, died.

(To be continued)

Distribution and Reactions of Hay Fever

WILLIAM SCHEPPEGRELL, A.M., M.D.
New Orleans, La.

The giant ragweed (Ambrosia trifida, Fig. 1) is generally supposed to be uncommon except in the Southern States, but this is not the case. In St. Louis, for instance, during a visit in 1923, we found a perfect hedge of these weeds on both sides of the road for ten miles from this city to one of its important suburbs. In Pennsylvania, the giant ragweed occurs in great thickets along the flood plains of the rivers, and on the slopes and uplands in great numbers. Even in the mountainous section of the Eastern States it is found in localities where the moisture is sufficient to encourage its growth.

In our classification of hay fever plants, the following are included in the minor groups: Goosefoot family (Chenopodiaceæ), buckweed family (Rumex), amaranth family (Amaranthaceæ), and plantain family (Plantagonaceæ). While these are of less importance than the members of the major groups, such as the ragweed and grasses, many of them have a very wide geographical distribution and, although they are less common causes of hay fever in most locations, they should not be omitted in the diagnostic tests (1).

In some sections, members of the minor groups assume the more important rôle, as for instance the Russian thistle (Salsola pestifer), a member of the Chenopodiaceæ group, whose pollen is an important factor in causing hay fever in the west intermountain district, and the rough pigweed (Amaranthus retroflexus) in Arizona and Southwest.

The pollen of the plantain (Plantago lanceolata) has been specially investigated by Harry S. Bernton (2) who found that five of a series of 116 hay fever subjects in the District of Columbia and vicinity were sensitive to this pollen. He found that preseasonal and seasonal treatment with the pollen extract gave a large percentage of relief.

I. S. Kahn (3) reports that eighty-five per cent. of hay fever cases in San Antonio are due to the pollen of the grasses (Fig. 3). This differs from a report

of the prevalence of hay fever in Northern, Eastern and Southern States in which the ragweeds form the most common cause of hay fever.

In the Sonoran belt in the Western intermountain district, a submountainous country, varying from an altitude of five thousand to seven thousand five hundred feet, H. J. Templeton reports that in his community at least three per cent. of the population suffer from hay fever, and that eighty-three per cent. of all the cases are due to the Russian thistle, the next most common cause being the sagebrush and chenopods.

When skin tests are negative, Ray M. Ballyeat (4) maintains that if these are repeated several times, they may become positive. He asserts that we should go into the homes of the patient and find out his exact environments from the cellar to the attic, and in his outdoor surroundings.

When hay fever patients give negative skin tests to pollens to which they are suspected of being sensitive, I. S. Kahn (5) uses an environmental method of causing the patient to remain in a closed room, and then go out of doors where pollen plates have indicated the presence of pollens. If the patient then succumbs to an attack of hay fever, he considers this a positive test. These cases are treated with desensitization in the usual manner, the results being about the same as in other cases.

FIG. 1.—Giant ragweed (Ambrosia trifida). It is common in moist soil from Quebec to Florida, and west to Nebraska, Colorado and New Mexico.

The skin test is not considered a reliable criterion for the determination of the amount of active substance in ragweed pollen extracts by J. H. Black (6) who prefers the reaction of the nasal mucosa of a ragweed individual. He also believes that none of the methods of standardization of pollen extracts are of value, and that the complement binding substance is apparently increased by treatment.

In a series of 424 cases reported by Andrew A. Eggston (7), 71.2 per cent. were sensitive to weed pollens, with symptoms in the latter part of August and September; 21.1 per cent. were sensitive to weed pollens and grass, with symptoms from the middle of May to the first of October; 6.7 per cent. reacted to grass pollens, having hay fever only in May and June, and one per cent. were sensitive to three pollens, which produce symptoms in April and early May. He found that 95.3 of the late summer cases were sensitive to the ragweed pollen which is very close to the proportionate report in our series of cases in the Department of Hay Fever and Asthma of the Charity Hospital.

In the discussion of fall hay fever, I. S. Kahn (8) states that this is frequently complicated in Texas by the presence of grass pollens, which are usually associated with spring hay fever, and that some of the cases of unsatisfactory results with the ragweed extract is due to failure to immunize against these, also he emphasizes the importane of the Scheppegrell method of pollen plates in this connection.

Piness (9) also calls attention to a similar condition in California where the Bermuda grass again becomes very active in the fall.

Some cases in which the cutaneous reactions are most marked give excellent results. In a case sent to me from Chicago in 1924, each injection was followed by a wheal over two inches in diameter, and which the patient insisted was as large as a "saucer," but which resulted in the patient, who had been a great victim of hay fever, being free of any symptoms the following year. Similar experiences are reported by Piness (10), Rackeman (11), and Bernton (12).

In the desensitization of allergic cases, the injections are usually given in the deltoid region, one arm being used, unless this shows signs of the previous injection, when the other arm should be used. Eggston (13) states that there is a special advantage in using one arm only, as he believes that a local tolerance to the extract is established after two or three injections are given into the same area, and that it is thus possible to increase the amount of extract more rapidly and with less danger of severe reaction. This local tolerance may be due to a retarding of absorption of the extract, or, as Coca maintains, to an exhaustion of the reactivity of the tissues, or probably to local desensitization of the tissues, as explained by Mackenzie. The greatest danger of reactions occurs from the accidental introduction of the extracts into the bloodvessel, or by giving the large doses in a highly sensitive area.

The coseasonal treatment of fall hay fever is advocated by Grafton T. Brown (14) in those cases in which preseasonal has been incomplete or in which there has been no preseasonal treatment.

This is also advised by Vaughan (15), who believes that since the nasal mucosa is irritated, the brunt of the allergic reaction during the pollen season or administration of pollen elsewhere as through the skin, would periodically distribute the pollen throughout other parts, thereby relieving to some extent the intensity of the nasal irritation.

When treatment is administered during the hay fever season, an attack of hay fever is frequently

attributed by the patient to the effects of the treatment. If the attack synchronizes with the increased pollen count as shown by the pollenometric plates (16), this is probably not the case. Constitutional reactions moreover are almost always associated with marked local reactions at the site of the injection, and usually follow within an hour or two of the injection.

In the administration of pollen extracts (17),

FIG. 2.—Pollen of giant ragweed. X 1000 diam.

Eggston reports that in cases in which the single pollen extract fails to give response, a mixture of pollens, which consists of all the pollens combined in the proportion to which the patient gave reactions, should be used. In the fall variety, particular attention is given to both forms of ragweed, the other reacting pollens being considered as minor factors. An autogenous polyvalent extract is used for the spring type, or grass cases. The general observations were that the patients receive better results when a polyvalent extract is used.

In the vasomotor rhinitis cases, desensitization injections were given if allergic reactions were demonstrated. The nonallergic cases responded very satisfactorily to the proper endocrine therapy. Several of the allergic cases gave better results when the injection and endocrine therapy were combined.

FORMS OF ANAPHYLAXIS

If we consider the susceptibility of certain cells to sensitization as a form of potential energy which is easily made kinetic by influences otherwise harmless (18), we can understand the mutual relationships of sensitization and the offending protein, while it also explains the association of hay fever and asthma with such factors as locality, barometric variations, and other conditions which may have a disturbing effect on the protein metabolism.

A large portion of the nonallergic type of hay fever shows indications of endocrine imbalance, and the question of the relationship of internal secretions to allergy is therefore pertinent. Undue taxation of the autonomic nervous mechanism through fatigue, toxemia, faulty metabolism, hypoendocrine or hyperendocrine function will result in sympathetic reactions, of which vasomotor rhinitis and allergy are related expressions.

The expressions of anaphylactic disturbances in hay fever, asthma, certain skin diseases and other manifestations of disturbed metabolism, vary within very wide limits and still more so in degree. We have cases, for instance, in which egg is the only offending substance in asthma and no other article of diet or even atmospheric changes will produce an attack. Other cases in which the common ragweed is the only offender in hay fever and then only to such a slight degree, that the paroxysm develops only at the very height of the pollinating season of this plant.

On the other hand, there are cases in which the offending proteins are extremely numerous. In some cases of hayfever, for instance, patients are sensitive not only to the tree pollens in early spring and the grass pollens in early summer, but also to the cheno-

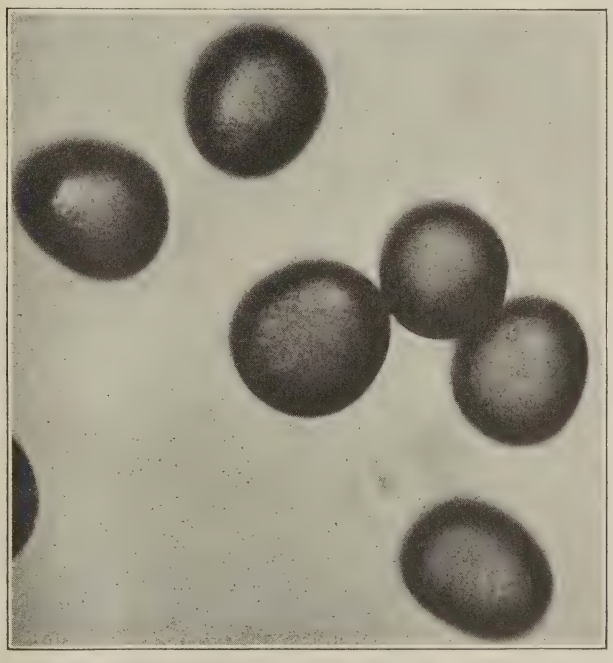

FIG. 3.—Pollen of Johnson grass. The grasses are a common cause of hay fever in all parts of the United States. X 500 diam.

pods and the ragweed, this completing the cycle of hay fever from the beginning of spring to the end of autumn; and some of these hay fever cases are sensitive not only to the above, but also to epidermal and food proteins, which tend to prolong their hay fever season through the whole year and thus establish the perennial type.

While the subjects of the underlying principle involved in the various manifestations of allergic diseases are still subject to discussion, fortunately the treatment of these conditions has made great advances in recent years. This applies specially to hay fever in which the intensive treatment with the glycerol ex-

tract (19) has given excellent results. It has definitely placed hay fever on the list of curable diseases, and the results now obtained compare favorably with those of other diseases.

The Treatment of All Diseases of Vegetable Parasitic Origin by Injection of Mercury and a Recent Important Modification

BARTON LISLE WRIGHT, M.D.

Balboa, Canal Zone

Commander, Medical Corps, United States Navy

In November, 1910, in either the *Medical Record* or the New York Medical Journal, I first published my conviction that in mercury we have a curative agent of superlative value for all of these diseases. Since that time I have had no reason to change my mind, though the brilliant results reported by me then and in succeeding years were not always obtained in all cases treated, yet they were so good as to warrant me in continuing its use.

It was my thought that the salt of mercury (mercuric succinimide) that I used by preference, could not be injected satisfactorily into the average adult male patient in doses larger than ninety-one milligrams (seven and a half grains).

I hoped and believed that sooner or later a compound of mercury would be developed that would permit of much larger doses, and that when found, its administration would be followed by better and more consistent results.

A few years ago, when Young published his first paper on the intravenous injection of mercurochrome 220 soluble, I was immensely pleased, and believed that (by me) long desired form of mercury had at last been developed. But the results obtained by Young and others, reported in current literature, have neither been better or more consistently obtained than those resulting from the deep muscular injections of mercuric succinimide given by me in a variety of infections, among which were included croupous and bronchopneumonia, typhoid fever, the socalled rheumatisms, scarlet fever, measles, colon bacillus infections of the blood stream, iritis, and various skin infections. I have from time to time given much thought as to why more consistent results are not obtained, and at last I have discovered it.

Mercury requires an alkaline media in which to combine and produce the chemical reactions, which I described fifteen years ago, and which are repeated below.

It is well known, and has been repeatedly emphasized by Crile, that the normal alkalinity of the body tissues and fluids is reduced by both disease and shock. The more severe the disease or profound the shock, the greater the reduction in body alkalinity, even acidosis resulting.

It seemed to me that the brilliant results reported both by Young and myself, must have occurred in patients in whom, for some reason, the body alkalinity had not been much reduced by the invading infection, and that the negative results occurred in those where acidity or acidosis had taken place, thereby preventing the chemical reaction taking place which results in complement fixation and the destruction of the invading parasites.

This reaction as expressed by me in my early papers was in two parts as follows:

1. Vegetable antigen+Hg.+complement=rapid antibody formation.

2. Vegetable antigen+antibody+Hg.+complement=complement fixation or rapid cure.

In some of my cases the cure was so rapid (seven hours) that I thought the reaction might be expressed as follows: Vegetable antigen +Hg.+complement= complement fixation.

From my recent experimental work I can now say, given an alkaline, or preferably a hyperalkaline body, and this may readily be obtained by the oral administration of sodium bicarbonate, that the chemical reaction within the patient, as expressed by the above formulæ, will take place with almost constant regularity, when mercuric succinimide in proper doses is administered, and though I have not used mercurochrome in these experiments, I see no reason why the results would not be the same following its administration.

From my recent results I am convinced that we have in this method the very best treatment now available for all the diseases of vegetable parasitic

origin, and perhaps for those of protozoan or other animal parasitic origin.

In treating acute infections, where the necessity for immediate treatment is urgently indicated, give by mouth sodium bicarbonate, three grams before the injection of ninety-one milligrams (seven and a half grains) of mercuric succinimide, two doses of two grams each during the rest of the day. If a second or third injection is required during the next few days keep up the administration of sodium bicarbonate giving six grams during each twenty-four hours.

In chronic infections it is desirable to start the patient on six grams of sodium bicarbonate daily, forty-eight hours prior to the first injection. Give second injection forty-eight hours following the first, and third injection seventy-two or ninety-six hours after the second. During this interval the sodium bicarbonate should be continued. Succeeding injections should be given every seventh day, starting bicarbonate of soda forty-eight hours before the injection and continue giving it throughout the day of injection.

Six or eight injections in most cases will prove sufficient, but in more resistant cases, such as tuberculosis, after the sixth or eighth injection discontinue the treatment for a month or six weeks, and then resume it.

From what I have seen I believe that this method will restore mercury to the front rank as an antisyphilitic agent.

An intriguing hypothesis in connection with this method is possible:

Is the problem one of physiological or biological chemistry, as I think it is, or have we bipolarized the medium (body) in which the reaction takes place, generating an electric current within the body destructive to all parasitic life?

If the future develops an affirmative answer to this question, then Crile's prophecy made in his London address some years ago has been fulfilled.

In conclusion, a three per cent. solution of sodium hyposulphite, applied to the gums by applicator, or used as a mouth wash twice daily, will quickly relieve any mercurial gingivitis that may develop.

ADDENDA

Additional information relative to the administration of mercuric succinimide following the first injection:

After the first injection of mercuric succinimide gm. 0.091 (gr. 7.5), succeeding injections should not contain more than gm. 0.065 (gr. 5.5), and in the dose and spacing of these succeeding injections the physician must be guided by the symptoms, if any, of mercurialism presented by the patient.

In females the first injection should contain gm. 0.065 (gr. 5.5) and the succeeding injections not more than gm. 0.052 (gr. 4.5).

The Prevention of Socalled Bathers' Ear

GEORGE B. McAULIFFE, M.D.
New York

Despite all the propaganda of aural hygiene we have every summer a large number of middle ear inflammations occurring among bathers. It would appear that the hygienic advice was faulty or incomplete, inasmuch as it does not prevent aural complications.

The inflammation varies from a mild tubal catarrh, with its annoying aural disability, to a severe tubotympanitis, with the sequel of mastoiditis. Salt water seems to bring more cases than fresh water—probably because most of the swimming is done in salt water.

Rigid inquiry rarely elicits the causal factor, because the result and cause are not obvious to the patient. The laity from time immemorial have felt that the trouble came from water getting into the canal, on account of the occasional temporary deafness which follows the retention of water in the fornix of the canal adjacent to the drum membrane. It is obvious, however, that the water gets into the Eustachian tube and tympanum. Why is it that this accident only occasionally happens? How does the water get into the tube?

In order to get some information on this subject I sent a questionnaire to the prominent amateur swimmers of the New York Athletic Club. They are all well known experts in swimming and diving. Their testimony is interesting. I received thirteen replies.

A. L. Downs has been swimming for twenty-eight years in salt and fresh water. After ten years of swimming he had a slight deafness and discharge which he attributed to the dirt in salt water. He was in the habit of blowing his nose after coming out of the water. The hearing of one ear is damaged. He has had no mastoiditis. He finds that swimming increases the secretion of cerumen. While diving he uses rubber plugs coated with vaseline. Tank swimming is not injurious if a frequent change of water is made. In his opinion, and in that of many of his associates, outdoor or salt water swimming causes more ear trouble than indoor or tank swimming. This is owing to the impurities in salt water.

J. L. Davidson has been swimming for twenty years in both salt and fresh water. He has never had any ear inflammation. He has been diving in competition for fifteen years. He never uses protective plugs. He had been told by professional swimmers, such as Matthew Mann, that if he did not use ear plugs in diving he would have ear trouble. So far he maintains they have been wrong. He finds no difference in the effect of salt or fresh water. He does not blow his nose when coming out of the water, but he blows out his ears (?). While he has never experienced any untoward effect from the swimming he believes that tank water is dirty and provocative of boils.

J. W. Smith is a swimmer of twenty years' standing in both kinds of water. He has never had any ear complications. He never uses any protection.

He finds that salt water increases the nasal secretion and thinks that salt water is more apt to affect the ears than fresh water.

G. W. Dahm has had fifteen years' experience in both salt and fresh water. He blows his nose after leaving the water. His hearing is slightly affected, although he has had no obvious inflammation. He never uses any protection.

H. Vollmer has been swimming in salt and fresh water for thirteen years. He never had any ear trouble until 1924 when he was kicked in the left ear during a game of water polo. The ear was treated and has given no trouble since. He never blows his nose after swimming. He uses lamb's wool as a protection. He prefers salt to tank water because there is generally too much alum in the latter.

C. LaForge has been a swimmer for five years. Six months after he began he had an otitis externa and an otitis media which was cured. His hearing is unaffected. He does not blow his nose after swimming. Diving never affects his ears. He likes to swim in tank water.

L. deB. Handley has been swimming almost daily for thirty years in both kinds of water. Once he had an accumulation of wax which caused an inflammation of his right ear (?) and both ear drums were broken by blows during a game of water polo fifteen years ago. Since then he has used cotton as a protection, putting a fresh piece in the ears on emerging from the water to absorb residual moisture. His hearing is good. He likes tank water and finds no difference between salt and fresh water in their effect on the ear.

C. Ross has been swimming for ten years generally in fresh water. He does not blow his nose after emerging. He uses no protection. He has had no ear trouble from swimming.

J. Curran after fifteen years of swimming has had no ear disease. His hearing is perfect. He does not blow the nose after leaving the water and uses cotton as a protection. He finds cold water increases the secretion of cerumen.

R. M. Rutter has been swimming thirty-four years. Fourteen years ago he had "ear trouble" which he does not describe. He attributed it to impurities in the water and thinks salt water more harmful than fresh. He does not blow his nose after swimming. He uses soft rubber ear protectors and maintains that his hearing is normal.

C. Trubenbach is a veteran swimmer of thirty-four years' standing. He had both membranes ruptured in water polo but his hearing is good. Diving never affects his ears. He uses cotton as a protection and also prefers tank water.

A swimmer, whose name has been lost, has thirty-two years of competition to his credit. He has been swimming altogether thirty-nine years. Eight years after he began he had otitis media which he attributes to diving and under water swimming. His ears were affected for twenty years but are all right at present. He thinks diving hurts the ears. Has always blown his nose after swimming. Used cotton as a protection and finds salt water more harmful to the ears than fresh water.

If we analyze these statements of swimmers, who know no more than the ordinary laity of the hygiene of the ear, we find that swimming rarely affects the ears. Most of the cases of ear infection are found in the infrequent swimmers—the summer bathers. It is noticed that salt water is more deleterious than fresh water. It may be that salt water which to fishes is a veritable soup, due to the pelagic plankton, is irritating if not septic. It is also seen that salt water causes a rhinal discharge which induces blowing of the nose. This gives the hypertonic salt water an opportunity to be forced into the Eustachian tube. Fresh water, if under proper tank supervision which looks after frequent renewals, sterilization with actinic rays or chemicals, is comparatively harmless, inducing occasionally a tubal stenosis when pent up in the tube by the difference in osmotic balance.

We find that the majority of swimmers do not blow the nose. Therefore, outside of swallowing when the water is in the mouth no opportunity exists for the entrance of fluid into the middle ear. Of course a perforation of the drum membrane will admit water into the middle ear if plugs or proper protective substances are not used. Rubber plugs coated with vaseline are occlusive. Wool, also, which has fat and is therefore not hygroscopic, is useful.

In a healthy ear the use of plugs is not necessary, as is seen in the statement of Davidson who has been in competitive diving for fifteen years.

SUMMARY

Of all these swimmers eleven maintain that diving is not injurious to the ears. One who swims under water and dives thinks that diving hurts the ears. Two of the three who blow the nose after emerging from the water have had ear inflammations. Two of the thirteen swimmers have damaged hearing. Five swimmers used no protection. Not one had any ear trouble. Five used cotton. Three of these had some ear affection. Five who used rubber plugs had ear inflammation of long standing. None had mastoiditis. Eight thought that tank water was good. Four thought it might be deleterious. Three of the four attributed the changes to dirt, one to superfluous alum. Two found swimming increased cerumen. Ten did not find this to be a fact. If we sum up these points we find: that diving does not affect the ears; that protective appliances are not necessary; that salt water is more harmful to the ears than fresh water for swimming by reason of its tumult which increases the chances of its being forced into the nasopharynx and tubes, or by reason of its provocation of nasal secretion—an effect which renders necessary the blowing of the nose with possible entrance of the salt water into the Eustachian tubes.

CONCLUSIONS

The conclusions drawn are: 1. That bathers should not swallow water while swiming because swallowing opens the tubes and the water may gain entrance into the middle ear. This effect is similar to that of a faulty use of the nasal douche. 2. When bathers come out of the water they should let the water drain from the nose. Blowing should be avoided. If blowing the nose and swallowing are interdicted no ear complication will occur. 3. That the only time an occlusive protector is necessary is when there is an open perforation or when the skin of the canal is irritated by the water. Rubber plugs or wool are the best protectors.

The Nature of Hemophilia and Its Etiological Treatment

HARALD v. SAMSON-HIMMELSTJERNA, M.D.
Reval, Esthonia

The following explanation of the hemophilic symptoms makes no assertion of bringing evidence that the causes fundamentally underlying hemophilia are actually such as will be explained, but it will be shown that there may possibly be one point of view, in which the apparently contradictory phenomena of this insidious disease may find an explanation.

How can we explain the remarkable fact, that the bleeder, at the time when the disease is manifestly evident (let us call this the time of the predisposition to bleeding in short), shows no signs of coagulation in the wound, that in the majority of cases the coagulation appears distinctly retarded even extravascularly at the beginning of the bleeding, that with increasing loss of blood and with increasing enrichment of thrombokinase in the escaping blood this approaches more and more the coagulation time of the normal individual, and finally even normal values are reached extravascularly, but that the wound keeps on bleeding irresistibly without the formation of a thrombus?

The blood circulating within the bloodvessels of a healthy person contains antiferments, which prevent coagulation within the bloodvessels under normal conditions. If the blood escapes from the bloodvessels, or if there develop within it the same conditions, such as are known as prerequisites for the formation of a thrombus, these antiferments are destroyed and coagulation can occur. According to my opinion, a substance is formed within the diseased tissues of the bleeder at the time of the predisposition to bleeding, which also exerts a conserving effect upon the antiferments in addition to an injurious effect upon the bloodvessels. Its action is purely limited locally and is confined to the site of formation of the antiferments, that is, the diseased tissue, or, what is the same, to the wound surface. As we can find no substance in the blood of the hemophiliac even during the time of the predisposition to bleeding that would be able to retard the coagulation of normal blood, we must assume that such is not poured out in the blood. This substance (let us call it the conserving substance) will also exert its influence at the wound surface when the extravascular coagulation during a hemorrhage shows fairly normal values as a result of the addition of thrombokinase from healthy tissues or tissues only slightly damaged. These facts force us to the conclusion that the tissues of the bleeder produce this conserving substance to a marked degree, that is, in a marked degree different from that occurring in the hemophilic patient. It is certainly striking that the internal organs bleed only very rarely in most bleeders, and therefore their bloodvessels must have a normal or almost normal structure. We must, therefore, differentiate between tissues that are severely, slightly and not at all affected by the hemophilia.

The tissues that are only slightly affected by the hemophilia produce, the less severely they are affected and hindered from the formation of thrombokinase through the production of conserving substance thrombokinase, which escapes into the blood stream the more readily, even following the stimulation of small losses of blood. We assume, that in the beginning there is a certain neutral intermediate stage, in which neither conserving substance nor thrombokinase is formed.

The tissues not affected by the hemophilia produce thrombokinase in an entirely normal manner, which can become active at the wound surface following an injury and even there lead to normal coagulation. It is a well known fact that the inoculation injuries inflicted upon a bleeder in the vast majority of cases bleed only for a short time, which leads to the conclusion that the outer layers of the skin are not affected by the hemophilia in most cases. These tissues that are not affected by the hemophilia, however, for some unknown reason, are not in a position to pour out thrombokinase into the blood, at least not in the majority of cases. Only the stimulus of a loss of blood, or, as will be shown later, the stimulus of an injection of blood, enable them to pour out thrombokinase abundantly. This anchoring of the thrombokinase in the tissues is also observed normally in birds: the extravascular coagulation proceeds slowly, whereas that at the wound surface proceeds rapidly. In the bleeder this relationship is plainly evident during the time of the periods of recovery; clinically, the patient appears healthy, but biologically he shows the first sign of danger—the escape of thrombokinase into the blood is deficient. Opitz was enabled to demonstrate experimentally this more difficult escape of the thrombokinase in the bleeder in the blood cells, which form thrombokinase just as do the other cells of the body.

During the period of the predisposition to bleeding the bleeder shows hemorrhages in the skin, the subcutaneous tissue, the joints, and in the mucosa of the nose and the mouth. If an external hemorrhage occurs, the wounds bleed in the characteristic uncontrollable manner. Therefore, in the majority of cases, we can consider these tissues so severely affected by the hemophilia, that they are not able to form thrombokinase in response to the stimulus of the loss of blood, and the described stimulus cannot even produce a neutral intermediate stage, in which the wound surfaces, like every indifferent rough surface must lead to the formation of a local thrombus as soon as the escaping blood contains normal amounts of thrombokinase—in other words, as soon as the extravascular coagulation has reached normal values. In these severe forms of hemophiliac disease, however, a simple remedy is effective: the injection of even a small amount of alien blood. As will be shown later, I consider this administration of alien blood at the same time as a stimulating remedy, and assume that it exerts a far more powerful stimulus to the formation and throwing out of thrombokinase than the stimulus of the loss of blood. The stimulus of the administration of blood apparently reaches the severely affected tissues in the majority of cases and there produces either a neutral intermediary stage, or

even the formation of thrombokinase. In the less severe cases, the stimulus from the loss of blood in a given case will reach even the tissues affected by the hemophilia most severely and produce there at least a neutral intermediary stage. According to my understanding, the facts mentioned speak in favor of the assumption, that in the tissues affected by the hemophilia not only is a deficiency of the thrombokinase formation to be expected, but that we must assume the existence of a substance that does not allow the thrombokinase of the escaping blood to become effective at the surface, which conserves the antiferments in a purely local way. The subject of the part played by the injury of the bloodvessels, to which has been ascribed a dominating influence by many investigators, will be discussed later.

It has been mentioned above that the tissues of the bleeder are affected by the hemophilia certainly in various grades of severity. I will now discuss this in greater detail. I can in no way subscribe to the view so often expressed, that the internal organs bleed rarely only because they are protected from external insults. We see the subcutaneous, articular, nasal and oral hemorrhages occur almost spontaneously during the time of the predisposition to bleeding, and in individual cases not even the slightest trauma is demonstrable. It is very evident that a severe attack of coughing, every act of vomiting, and even any act of difficult defecation may exert much severer strains upon the internal organs than the frequently problematical, minimal traumas which cause the diseased tissues to bleed. Hemophilic hemorrhages occur rarely in the organs that have an abundant blood supply, like the lungs, stomach, and intestine, and these organs are healthy or only slightly affected by hemophilia in the majority of bleeders. In some bleeders we see the sudden occurrence of most severe renal hemorrhages without any visible cause. These very kidneys are protected to an exceedingly great degree from external insults far better than the rest of the internal organs, with the exception of the brain, the spinal cord and the bone marrow. In such a case we must assume that the kidneys are seriously affected by the hemophilia in the same way as the deeper layers of the skin or the articular surfaces. Naturally, the thought, that the different organs in one and the same bleeder may be seriously affected by the hemophilia during different periods of the predisposition to bleeding, cannot be easily set aside. But how can we explain the fact, that in the bleeder we not rarely see the hemorrhage cease after slight injuries, and yet the extravascular coagulation is distinctly retarded? Either the injured tissue is not at all affected by the hemophilia or only to a very slight degree and produces thrombokinase in a normal or almost normal manner, or the injury has occurred accidentally in the initial stage of a period of recovery, in which even the tissues severely affected by the hemophilia produce thrombokinase in a normal manner without being able to pour it out into the blood. Special attention is called at this time to the striking periodicity of this malady.

I once examined a bleeder, who several days before had a medium sized subcutaneous hemorrhage, which appeared without any recognizable cause. To my great surprise it was found, that a small wound made by me on the extensor surface of the arm bled only eight minutes and that the extravascular coagulation proceeded in an absolutely normal manner. Several months before that the patient bled for almost a day from a very small wound on the finger. The coagulum of blood showed the loose consistency characteristic of bleeders and swam freely in the expressed serum. It appeared to me unlikely that the subcutaneous hemorrhage mentioned could have poured out such an abundance of thrombokinase with a normal extravascular coagulation, as, in the first place, the hemorrhage was not severe, and in the second place, it had already appeared several days before. Several days after the examination the mother of the patient informed me that a subcutaneous effusion of blood had developed at the site where I made the wound. The slight pressure exerted by me while lifting a fold of the skin was sufficient to produce ruptures of the bloodvessels. After a short time the tendency to hemorrhages disappeared completely, and I cannot believe that the small, lively patient, two and a half years of age, did not occasionally slightly bump himself at some time during the long convalescent period of about six weeks. After about six weeks another aggravation in the condition occurred with numerous subcutaneous hemorrhages and an articular hemorrhage, similar to the one that occurred before. Unfortunately, the little patient slightly injured his tonsil while at play and died from a hemorrhage. I am sorry to say that I was enabled to examine the patient only once and I therefore cannot say whether the extravascular coagulation in this case was normal or not. The fact that during the examination almost normal conditions (a bleeding period of eight minutes instead of one to three minutes) prevailed at the wound surface, whereas there was distinctly demonstrable a vascular injury which disappeared later.

I believe that I may attribute to the fact that the bloodvessels injured by the conserving substance remain fragile for a long time, and that the components of this substance which injure the bloodvessels has a persistent action long after the substance itself has disappeared from the tissues and the formation of thrombokinase has begun. By some investigators, the vascular injury, but according to my conception, the components of the conserving substance that injures the bloodvessels, are ascribed the dominating part in the phenomenon of the obstreporousness of hemophilic bleeding. Admittedly, there are disease conditions in which a vascular injury alone leads to serious hemorrhages, and one needs to think only of the hemorrhages in scurvy. What is more natural than to assume the existence of the same cause in the incontrollability of hemophilic hemorrhage. I believe that the undoubtedly existing components of the conserving substance that injure the bloodvessels can be given only a subordinate part, and that for the following reason. The injection of only a few cubic centimetres of alien blood during a hemophilic hemorrhage leads to the desired result in most cases in a short time, a thrombus forms, and the hemorrhage ceases. I believe that it is entirely unimaginable that we could heal a vascular injury by the injection of this small amount of blood in a very short time. We see, as the case cited by me shows, that the vascular injury disappears only after the period of improvement has lasted several days. The effect of adrenalin, which would be able to exert a rapid effect upon the

vascular walls from the injection of the alien blood, does not deserve consideration. But we must certainly admit a moderate prolongation of the bleeding period as a result of the vascular injury, as I have also observed this in the case cited by myself.

It might be well to mention the fact, that definite cures of this malady have been observed when the patients have been exposed for long periods of time to the effects of mountainous or tropical climates. What have these two factors, mountainous and tropical climates, in common with each other? So far as we can determine, only the one element—intensive insolation. The extensive surface of the external skin, of which the deeper layers are very often affected by hemophilia, is the tissue that is mostly and most immediately exposed to the sun, and it may therefore be assumed that solar irradiation has the ability of preventing the further formation of the conserving substance in the skin, without the development of recurrences. But some other curative influences upon the other tissues that are affected by the hemophilia must emanate from the large surface of the skin, or otherwise some isolated articular hemorrhages must be left behind. I wish to call attention to the fact, that it has been very generally noticed that the skin of many bleeders is abnormally tender. In this connection, this finding deserves special consideration and indicates that this organ might be accorded a special significance in the pathogenesis. Attention is called to the possible favorable influence upon this disease of suitable heliotherapeutic measures (mercury quartz lamp).

Another phenomenon also deserves closer consideration. If we inject only small amounts of alien blood into a bleeder, who shows practically normal extravascular coagulation during the hemorrhage and whose blood must therefore contain normal amounts of thrombokinase, the best result is often seen: the bleeding ceases in a short time, and a thrombus forms. This injection of blood is made originally with the intention of administering to the blood of the bleeder a considerable amount of thrombokinase and thereby to produce coagulation in the wound. According to my conception this belief is incorrect. If we inject this alien blood at the moment when the extravascular coagulation already shows normal values, we in no way change thereby the thrombokinase content in the blood of the bleeder, as what we inject is blood having the same thrombokinase content as the escaping, already extravascularly, normally coagulating blood of the bleeder. But with the injection of blood we have done something entirely different than administered thrombokinase—we have injected a foreign protein, a well known shock producing body. This shock body acts much more intensively than the stimulus from the loss of blood and reaches even to the tissues that are severely affected, where the further formation of the conserving substance is inhibited, and there results at least a neutral intermediary stage, in which the wound surface acts as an indifferent rough surface to which thrombi may attach themselves as soon as the escaping blood shows a normal extravascular coagulation. Recent literature has shown distinctly enough how the parenteral administration of a shock body can considerably accelerate a slowly progressing reaction of an organ or system of organs in a short time. The production of thrombokinase in the healthy tissues occurring as a result of the stimulus of the loss of blood, and the effect upon the tissue affected by the hemophilia in the sense of a formation of thrombokinase, we can consider as only a tardy and insufficiently intensive reaction.

The results from röntgen irradiation of the spleen must also be considered as an effect of shock therapy. A large amount of thrombokinase is certainly set free through the functional disturbance of the spleen following the irradiation and the massive destruction of the red blood corpuscles incident thereto. But this factor does not appear to me to be the important one. It has been known for a long time that the intramuscular injection of the patient's own blood, as a result of which there is a destruction of the individual elements of the blood, develops a shock therapy. With irradiation of the spleen large amounts of red blood corpuscles are suddenly destroyed, the decomposition products of which may well act like a foreign protein (shock body), just as do the decomposition products of the patient's own blood following their intramuscular injection. It would be interesting to attempt a peroral shock therapy at the beginning of a tendency to bleeding for the purpose of preventing further hemorrhages.

On the basis of the observations mentioned above and the fact that the thrombokinase is present in the blood of the bleeder in individual cases even in large amounts without a loss of blood having preceded it, we can state that the true nature of this disease lies neither in a deficient formation nor in a deficient escape of the thrombokinase, but in an involvement of individual tissues which occurs in attacks and is characterized by the production of a conserving substance that injures the bloodvessels.

Now to the consideration of the treatment. An etiological therapy must be able to permanently prevent the formation of this conserving substance, which we believed must be assumed to be the cause of the imminent hemorrhages. At the present time we are still entirely ignorant as to what force produces the regularly observed spontaneous periods of improvement, so that we cannot artificially strengthen or produce it. We have discussed the results to be possibly expected from heliotherapy and shock therapy.

But there is also another possibility of forcing this sinister disease into the circle of diseases that are definitely amenable therapeutically. From time immemorial, the remarkable fact has been noted that the women of bleeder families have remained free from this disease throughout their life, but that their sons are afflicted with it with great regularity. Recent investigations, however, have shown that certain anomalies (resistance of the red blood corpuscles, an increased chlorin content, and the absence of trypanocidal substance) are demonstrable in the blood of women in bleeder families, but a manifestation of the disease, as characterized by hemorrhages that threaten life, have never, or, to be more careful, almost never been observed. This circumstance leads to the conclusion that the female body has at its disposal very powerful protective bodies, which prevent a manifestation of the disease, that is, make the formation of conserving substance impossible. This thought led me to attempting some experiments on

the influencing of the organism of bleeders by ovarian hormones, and thereby, to a certain extent, to produce the condition of an artificial hermaphroditism. At first I wanted to attempt it with a peroral administration of ovarian hormones, but with their failure there still remained the implantation of an ovary. At my request chemical houses manufactured an ovarian preparation by most careful methods, which contained all the hormones of the ovary of the cow. I selected this animal because hemophilia has been observed in cattle and I therefore hoped to find in them a specially effective preparation. In order to be able to study any possible developing undesirable effects, I first tried the experiments on myself (age thirty-seven years). During the first four weeks I regularly took by mouth an amount (divided into four portions) that corresponds to 3.0 grams of fresh ovarian substance. During the next two weeks I increased the daily amount to one corresponding to 6.0 grams of fresh ovarian substance, and during the last eight weeks a dose corresponding to 15.0 grams. I took this preparation regularly in the forenoon at 7 and 12 o'clock, and in the afternoon at 5 and 10 o'clock, in order to obtain as uniform an effect of the ovarian hormone as possible throughout the entire day and night. Exactly thirty days after the beginning of the experiment I noticed a slight sticking sensation in both nipples, which lasted several hours. These sticking pains repeatedly recurred later during the period of the experiment, about every two to five days. I was unable to discover any hypertrophy in the region around the nipples or in the nipples themselves. Naturally, one cannot definitely decide whether the slight sticking pains in the nipples should be considered as being due to the ovarian hormones or not, but for me it is certainly noteworthy that, as far as I can remember, I never before experienced such sensations. In spite of the most careful selfobservation, I have not been able to find any other perceptible effects.

As far as one can determine from a single observation, there are no noteworthy undesirable byeffects in the adult male organism from the continuous peroral administration of ovarian hormones. I conducted no experiments on the organisms of children. Some opinion may, however, be formed from a large series of experiments on animals (1). Krause implanted into young male guineapigs different sized pieces of ovaries from the same species of animals, some of these animals having been partially castrated. After variously long periods of latency distinct female sexual characteristics, which were expressed in a hypertrophy of the teats and milk glands, developed in one third of the cases. In not a single case, however, could a suppression of the development of the male sexual characteristics be demonstrated. It appears to me that these experiments suggest the propriety of administering ovarian hormones also in children.

I am sorry to say that I must leave to others the task of testing experimentally the correctness of the above mentioned theories as to the nature of hemophilia, and, unfortunately, I have been denied the privilege of testing the applicability of the above mentioned therapeutic possibilities on patients. Anxiety and the lack of understanding in the few bleeders whom I have been able to reach have robbed me of this possibility. Before any final opinion regarding the value and futility of the therapeutic measures indicated can be rendered, these experiments would have to be carried on for a long time.

Immunization Against Scarlet Fever*

HARRY S. SNYDERMAN, M.D.

Philadelphia

Scarlet fever is one of the many serious diseases of childhood. The mortality is rated fifth among the most fatal ailments in children under ten years. The complications add to the dread of this disease, and the late appearance of renal and of cardiac sequelæ and of frequent involvement of the ears and glands increases its gravity.

To determine the susceptibility to or the immunity from the disease in any individual we now have the Dick test, which is similar to the Schick test, used for determining susceptibility or immunity to diphtheria.

The Dicks have obtained a toxic filtrate by growing the scarlatinal streptococcus on blood agar slant. The condensation fluid which is passed through a Berkfield filter contains the toxin. This fluid injected into normal persons gave a positive reaction in those who never had scarlet but who are susceptible and gave a negative reaction in those who had the disease.

The Dicks further report that they obtained active immunity in persons who were positive after giving them three injections of ascending doses of this filtrate, properly diluted.

The Dick test consists of an intracutaneous injection of 0.1 to 0.2 of the soluble toxic filtrate, properly diluted.

The dilution varies from 1-500 to 1-2000 in physiological sodium chloride. It is more stable than diphtheria toxin. It can be kept under proper temperature for a long period and is therefore distributed already diluted and ready for use.

The reaction can be interpreted differently, depending upon its severity and the area involved. Some classify it as slightly positive, where the area involved is less than two cm. in diameter and without swelling; positive where the area involved is from two to three cm. in diameter and is bright red in

*Read before the Southeastern Branch of the Philadelphia County Medical Society, April 1, 1926.

color and there is also some swelling. The reaction is said to be strongly positive where the area involved is more than three cm. in one or both diameters and intensely red and is associated with marked swelling and induration.

Another classification which is used by many depending upon the area involved and the amount of induration is (x) (xx) (xxx) and (xxxx). I find this classification the most convenient and in my work I have called any redness at all a positive reaction. I did this because I wanted it to be absolutely negative over a period of time, so that the patient could be retested after a period of observation.

The local effect of the scarlet fever toxin is more rapid than the Schick. It begins to appear from four to six hours after the inoculation, at first as a small circular area of erythema, which increases in size and reaches its maximum between eighteen and thirty-six hours.

After reaching the maximum it begins to subside and even the most severe positive does not persist more than forty-eight hours. The bright red color becomes dull and begins to fade. I have had many positives appear within thirty minutes after injection and these all proved to be strongly positive and persisted for forty-eight hours.

The negative reaction shows no change at the site of the toxin injection or at the site of the control; these persons we believe are immune to scarlet fever.

RESULT OF THE DICK TEST

The test was applied to children varying in age from three to sixteen years. In all I have tested 1,467 persons on whom I did over ten thousand tests within the last sixteen months, with material obtained from different biological houses, with the following results:

Age	*Total Tested*	*Dick Positive*	*Dick Negative*	*Percentage Positive*
3- 4	197	88	109	45
4- 5	224	83	141	37
5- 8	364	128	236	35
8-10	251	76	175	30
10-12	202	47	155	23
12-16	229	40	183	20
	1467	462	999	31

The table above represents the results of the tests on children in public institutions; 156 tests done on private patients and the private school which gave a much higher percentage.

Age	*Total Tested*	*Dick Positive*	*Dick Negative*	*Positive Percentage*
6-16	156	104	52	66

Results in families: Wherever I obtained a positive and a negative in the children of the same family the negative was always in the older child but usually they were positive in all. In one family where I treated a scarlet fever case I tested the rest of the children. They were all negative with the exception of one brother two years older. This child developed scarlet fever three weeks later. At no time in my experience did the test prove positive where there was a positive history of having had scarlet fever.

ACTIVE IMMUNIZATION WITH SCARLET FEVER TOXIN

I have injected all children who gave a positive reaction. Four injections were given at weekly intervals. All children were under the care of trained nurses and temperature was noted every three hours for forty-eight hours. The local reaction consists of redness and swelling at the site of injection and appears about thirty-six hours later. The first injection gives the severest reaction, though the following injections are much stronger. In a small percentage of children injected the local reaction was rather severe and the children developed temperatures from 100° F. to 102° F.; the arm was red and much swollen. In four cases the arm was inflamed from shoulder to finger tip, while in two instances I noted a scarlatinal rash, covering the entire body with sore throat and marked constitutional symptoms. This now can be eliminated by adding soap solution with the toxin.

DURATION OF IMMUNIZATION

Group 1.—Numbering 136 children, were injected. Children under six received 100, 250, 500 and 1000 skin test doses; children from six to ten, 250, 500, 1000 and 3000. Forty per cent. of these became negative at the end of two weeks and fifty-four per cent. at the end of six weeks. At the end of three months the percentage became less and at the end of fifteen months only forty-one per cent. were negative.

Group 2.—One hundred and seventy children were injected. Children under six received 250, 500, 1000 and 3000 skin test doses. Children from six to ten years 500, 1000, 2000 and 4000. Children from ten to sixteen years 500, 1500, 3000 and 6000. Of these sixty-four per cent. were negative at the end of two weeks and seventy-three per cent. at the end of six weeks, while at the end of four and one half months the number of negatives began to decrease and at the end of thirteen months fifty-four per cent. were negative.

Group 3.—One hundred children under the age of six were given 500, 1500, 3000 and 6000 skin test doses, children from six to ten years, 1000, 3000, 6000 and 12,000; children from ten to sixteen years 1000, 4000, 8000 and 16,000. In retesting, eighty-six per cent. were negative at two weeks and ninety-one per cent. by the end of six weeks. After six months the number of negatives began to decrease and at the end of thirteen months sixty-nine per cent. were negative.

Group 4.—Fifty-six children were injected with 100, 250, 500 skin test doses. Of these forty-two per cent. were negative at the end of two months and only seventeen per cent. were negative at the end of eight months.

Group 5.—Twenty-two children were injected with single doses of 5000 skin test doses. Of these eighty-two per cent. were negative at the end of ten days, and at sixty-eight per cent. at the end of one year. The reactions, however, are more severe.

CONCLUSIONS

The Dick test is a reliable index of determining the susceptibility or immunity to scarlet fever.

Determining the efficiency of active immunization with scarlet fever toxin.

The older the individual the greater are the number of skin test doses required to produce immunity.

Immunity is produced within two weeks after the last injection.

It is not a permanent immunity.

The individual who becomes negative and then positive requires much larger doses to become immune and in such cases immunity is of a shorter duration.

During an epidemic, we have the opportunity of using a valuable preventive agent, as immunity which lasts at least six months and much longer in some instances if produced.

A single injection of a large dose will produce an early and lasting immunity.

2010 Pine Street.

Rectal Feeding

CHARLES J. DRUECK, M.D.,

Chicago

(*Concluded from page* 288)

OPIUM IN THE NUTRIENT ENEMAS

Opium in the form of laudanum (from three to twenty minims) may be added to the nutrient when irritation exists, but it must be remembered that opium inhibits peristalsis and thus favors retention of the enema, and also interferes with its absorption. Whenever this drug is resorted to, the dose must be guarded and its action watched. If the nutrient enemata are continued for a protracted period and the rectum becomes irritated, the opiate often acts better if introduced from one half to one hour earlier. When thus administered separately, the volume is so small that it can act locally before the larger nutrient enema is given. The deodorized tincture of opium or McMunn's elixir may take the place of laudanum.

FOODSTUFFS SUITABLE FOR RECTAL FEEDING

Not all substances administered by mouth are available for rectal feeding. Starches and most of the fats rarely are absorbed from the rectum. Starches partially converted into sugar are absorbed more readily, but not sufficiently so to be serviceable as food. Malt extracts may possibly sometimes be absorbed. Fats and oils are rendered worse than useless by coating the rectal lining as well as the food, thus preventing absorption of the latter. Attempts at saponifying or emulsifying the fats have given very poor, or at least doubtful, results.

It is important to select only such substances for rectal foods as will be entirely, or nearly, absorbed, because all residue acts as a foreign body. However, it has been found that many albuminous foods, although absorbable, act as irritants when given in too great a degree of concentration. Pure peptones, for example, must be diluted with two or three volumes of water or some bland substance. Some albumens, such as of eggs or that made from chopped meat, may be absorbed by the rectum undigested; but even these are better when partly pancreatized.

Albumen is very slowly, if at all, diffusible and must previously be changed into albumose. This may be accomplished by adding pepsin or pancreatic extract to the injection, either some time before administering and allowing digestion to take place outside the body or by adding the ferment just before giving the clyster and then allow digestion to proceed within the bowel. Catillon, experimenting along this line on dogs, found that the animal fed (rectally) on unaltered egg lost weight and barely kept alive, while the one receiving eggs combined with glycerin and pepsin retained its normal weight and apparently its health. After thirty-seven days the pepsin was omitted, whereupon the dog gradually lost weight.

ITEMIZED CONSIDERATION OF FOODSTUFFS

Pancreatized meat.—Pancreatic extract in some form may be employed in preparing proteid food; but it must be fresh, as it does not keep and so is likely to act as an irritant. So, also, glycerin extracts of pancreatin will not do, on account of the aperient action of the glycerin. Leube suggests the addition of one part of fresh pancreas to three parts of beef as the best proportions, the pancreas and meat being finely minced and triturated, after the addition of a little water, until it forms a paste. All adhering fat must be carefully removed. A large nozzle syringe is required for injecting the mass. The principle underlying the procedure, according to Leube, is, that digestion begun outside is continued within the colon; it being only rarely that the substances are absorbed immediately, while in this shape they may be retained in the bowel for as long as ten hours without detriment.

Mayet suggests practically the same formula, only that he adds the yolk of one egg and allows the mixture to stand two hours before administering. Occasionally it is recommended to add to the beef mixture some hydrochloric acid and also milk, but the acid is altogether too irritating for intestinal digestion, and artificial digestion must be carried on outside the body.

Blood.—Dried beef blood has been used as a rectal food, but is not practicable, for it usually clots within the rectum and thus prevents the absorption of other substances. Fresh defibrinated blood, four ounces every six hours may be used, but it is not recommended.

Milk.—Milk is one of the most satisfactory rectal foods. It should be free of all its cream, and digestion must not be too far advanced outside the body.

Eggs.—Egg albumen is one of the best, if not actually the best, ingredient for rectal feeding. It is absorbed from the rectum, even if unchanged, but it is better if predigested with peptongenic or pancreatic powder. Ewald says that egg albumen, unpeptonized, is absorbed as readily from the rectum as commercial peptone, but that peptonized egg albumen

is taken up much better. The addition of fifteen grains of salt to each injection aids absorption, although it sometimes irritates and, hence, must be used with care. The yolk of the egg is not used, because it contains so much fat mixed with the albuminous matter as to be practically useless. Fats can be absorbed only by the villi of the small intestine, and in no other part.

Glucose.—Invert sugar is absorbed in dilute solution. If given in concentration it irritates the mucosa and stimulates expulsive peristalsis. Leube recommends three hundred cubic centimetres of a fifteen per cent. solution as a maximum.

Stimulants.—The agents of this nature employed in rectal feeding are alcohol and coffee. Each represents a different class, with its specific indications.

Alcohol.—When used for rectal feeding, the alcohol must be good liquor, well diluted; the brandy, one half to one ounce being added to the portion just before it is administered, but after the process of predigestion. Being irritants, large amounts of alcoholics must never be added. Many times a small injection of half an ounce of whiskey or brandy in one and one half ounces of water will be retained and absorbed, when a larger amount of fluid with the liquor incorporated would be expelled. Undiluted liquor added to milk sometimes causes a precipitate by coagulating the casein that has not been pancreatized; however, no solid matter, even if in the form of a fine precipitate, is of use in the rectum, for it merely acts as an irritant.

Alcohol stimulates the bowel and increases the absorbability of proteids. One of the strong points in employing liquid peptones is, that they contain the alcohol well diluted—about fifteen per cent.—together with the same percentage of proteids and carbohydrates.

Coffee.—There are times, especially in postoperative treatment, when it is desired to combat shock, even more than to supply nourishment, and here a pint of good strong, black coffee, containing about five to seven grains of caffeine, will afford prompt and effective support. Whenever such stimulation is needed, the pint of coffee may be substituted for the nutrient enema. Coffee may be given much more freely than alcohol, although, of course, all stimulants are really irritants and, if introduced frequently, will render the bowel intolerant.

Here is a good formula for a nutrient enema containing a stimulant:

Beat the whites of two eggs with a tablespoonful of cold water, add half a teacup (four ounces) of a twenty per cent. glucose solution, in which one teaspoonful of starch has been boiled, a wineglass of claret or half an ounce of brandy, and a teaspoonful of peptone solution. Mix at a temperature not high enough to coagulate the albumen (Ewald), I may add that some authorities prefer claret to brandy because of its astringent effect.

ABOUT EMULSIFIED FATS

In the selection of a food for artificial feeding the caloric units which it represents obviously is important, and it would appear that fats and oils would be preeminent. However, clinically it is found that fats are not only not absorbed, but that when administered, they tend to coat the mucosa and the other food, and, thus, prevent absorption. This is most unfortunate, because a given amount of fat produces twice the energy that does the same weight either of proteid or carbohydrate food.

Attempts have been made to saponify the fats before their administration, and Edsall and Miller have carried out some extensive experiments along this line; but they were unable to find a soluble soap that did not contain so much alkali as to make it markedly irritating to the bowel.

The only way of giving fats is in the form of emulsion; but in using milk and the yolk of egg, it is found that the proteids entangle the fats in the coagulum and stop digestion. With the artificial emulsion much better results have been obtained. Malted milk and pancreatized milk have proved very satisfactory, because the fats are very finely divided by these agents. Either of these two powdered milk preparations named—half an ounce dissolved in five ounces of saline solution—usually will be well absorbed, and not irritate the bowel. Considerably more fat is absorbed from a preparation of this kind than might be expected.

I, myself, have had good success with a mixture consisting of half a pint of milk and two eggs (entire) given at one feeding, with the next injection consisting of pancreatized meat solution. By alternating these foods, the patient receives all classes of food substances.

NUTRITIVE VALUE OF ENEMATA

Boyd (6) shows that the patient's capacity of absorption more than the quantity of material injected determines the food value of the enema. A careful watch should therefore be kept to see that no unused portions of the clysters remain within the bowel to decompose and cause irritation. He advises an enema of yolks of two eggs, three grams of pure dextrose, half a gram of common salt and three hundred grams of pancreatized milk. This mixture represents about three hundred calories and if given four times in twenty-four hours makes a total of 1,200 calories, of which 240 to 640 calories may be absorbed.

The amount of nutrient injected each time must be determined for each patient. Some can retain not more than three or four ounces of liquid, and then the clysters must be given more frequently—perhaps every four to six hours. Others will hold comfortably up to eight ounces, and these need not be fed oftener than two or three times a day.

When the enemas are given at frequent intervals it is always necessary to add some opiate, since the rectum is sure to become irritated. However, almost always we shall be obliged to add opium after the first few days or a week, and, as the dose must gradually be increased, it is well to begin with the smallest possible dose, say, five minims of the official tincture.

Sometimes instead of filling the bowel with several ounces at one time it is better to use the continuous drip method. The vessel containing the nutrient enema is suspended one foot above the level of the rectum and the flow tested 50 to 60 drops per minute. The material in the container must be kept at a uniform heat of 120° F., which, with a thirty inch connecting tube, will deliver the enema at 100° F. in the rectum. The catheter should be removed from the rectum after each feeding because this continuous

drip must not be kept up continuously. This method will be found indicated in persistent vomiting and acute hemorrhages.

NUTRIENT SUPPOSITORIES

Suppositories sometimes are used for conveying the pabulum, the most common articles incorporated being evaporated predigested milk or meat juice, with cacao butter as the vehicle. They possess no effective value over enemata but may prove useful where feeding is to be continued for a longer time.

CONCLUSION

In concluding I will add that I do not wish it to be understood that rectal feeding can entirely replace the normal method of ingestion of food, but I do insist that in the proper class of cases, as indicated above, where complete rest of the stomach for a few weeks or less may mean the saving of life, this manner of supplying nutriments will sustain the patient and occasionally even add to his weight. Hunger and thirst are the most annoying symptoms experienced for a few days, but after that the patient is relatively comfortable. The tongue remains clean and moist and the longing for something to eat diminishes and even disappears. But this point I would emphasize—a large part of the success in this work depends upon the doctor's familiarity with the method employed and his skill in carrying it out.

Backache—Its Etiology and Pathology

SAMUEL KLEINBERG, M.D., F.A.C.S.

New York

Backache is one of the commonest complaints which the physician is called upon to treat. A great many women and many men suffer from pain in the back and disability resulting from a wide variety of constitutional and local conditions. In men, particularly laborers, backache is due more often to some local pathology than to systemic disturbance.

Since the subject of backache lends itself to extensive discussion, as it is symptomatic of many diseases affecting the tissues of the chest, abdomen and back, we propose to limit ourselves to a consideration of a few conditions in which backache is either the chief complaint, or one of only three or four important symptoms. We desire further to consider this subject especially in its relation to industrial injuries.

FRACTURE OF THE SPINE

In this lesion pain in the back is an important symptom; it appears immediately after the injury, and persists for months and sometimes years. It is usually the main complaint, and to the patient the earliest evidence of an injury to the back. The pain, which is ordinarily of moderate severity, is increased by all motions of the body, and especially by forced bending. It is relieved partially or even completely by rest or by support of the back. Immediately after the injury it may be intense or mild; in the later stages it is not very severe, but it is disabling.

The pain is referred very definitely to the site of the injury and is, therefore, diagnostic of the location of the fracture. The painful area is located immediately over the spine and over a short distance on either side of it, and is rarely more than two or three inches square. The pain is stationary; if it shifts about to any extent one may be certain that it is not due to fracture of the spine, unless there are multiple lesions. This localization of pain is an essential feature of the symptom group. The patient always knows definitely where the pain is felt and can point to the spot with one finger. When asked to indicate where he feels pain, there is no hesitation on his part; he does not say "Wait until I see," and does not move his body to make sure of the location. He points promptly to the painful region, which is directly over the injured vertebra.

The interpretation of pain in the back as indicating spinal fracture is facilitated by the presence of other important symptoms, viz., deformity, tenderness, stiffness of the back and positive röntgenographic evidence.

The preceding discussion refers particularly to fractures of the bodies of the vertebræ. In single or multiple fractures of the transverse and spinous processes in which the vertebral bodies are uninjured, there is always a history of a direct blow on the back. The pain may be very mild and not very disabling, but it is always localized. We have seen several instances in which there was no pain whatever. On the other hand, the pain and disability may persist for many months, as it has done in a number of patients under our care. The exact diagnosis can be surmised from the history and physical examination, but can be established only by röntgen ray pictures.

SPONDYLOLISTHESIS

This is a partial or complete dislocation of one or more lumbar vertebræ. Usually there is a forward subluxation of the fifth lumbar vertebra. The chief pain is in the middle of the lower lumbar area but is not narrowly localized; the patient complains of pain in the lower part of his back without pointing to any one spot, as is the case in fracture of the spine. This fact is explained by the nature of the lesion. The essential feature in this injury is, to be sure, a dislocation or subluxation of the fifth lumbar vertebra. Nevertheless, a large number of ligaments connecting the lumbar vertebræ to each other and to the sacrum and iliac bones are injured. The muscles of the back are stretched; the fibres of some may be

torn. The inclination of the pelvis is changed. The balance of the trunk, the function of weight bearing, the posture of the patient, in fact, the whole mechanism of the spine and its functions are altered. Thus, due to the large number of structures injured in this condition the pain is felt over a wide area. The characteristic objective findings in spondylolisthesis are a hollow above the sacrum and a röntgen ray appearance which, as we have emphasized several times, is pathognomonic.

If this condition is the result of an injury, the backache appears immediately or very soon after the accident, and is continuous and disabling. In the congenital cases, it may be very mild and usually is entirely absent until the patient suffers some injury of the back, after which it is persistent. It is, therefore, logical to conclude that, whenever there is severe pain in a case of spondylolisthesis, the lesion was either caused or aggravated by an injury; that is, the presence of severe pain is proof that there was an accident.

SCIATIC SCOLIOSIS

This is a painful condition in which the body is inclined forward and to one side. The attitude of the trunk is characteristic. It is inclined sharply to one side, the iliac crest (hip) on the opposite side is prominent and there is incurvation of the lateral border of the chest and abdomen. The inclination of the trunk is usually away from the side of the lesion, though it may be to the same side.

The special feature of this peculiar posture is that it is always present and marked during standing and walking; when the patient sits down, the deformity is greatly diminished and sometimes disappears, while when the patient is prone it usually disappears entirely, especially after a little rest. In only the chronic and very severe cases does the attitude persist when the individual lies down. There are no fixed or morphological changes in the vertebræ and the deformity of the spine is entirely postural. The curvature disappears as soon as the pain is relieved. The patient cannot control or correct his posture, which changes only when he changes his position from activity to rest or vice versa. Sometimes when the patient makes a strong effort to correct his deformity and moves his body forcibly, he may push it over to the opposite side; he rarely succeeds in straightening himself completely and remaining so.

The pain may be due to a variety of conditions in the back, pelvis, buttocks and thighs. It is most frequently due to a sprain or similar derangement of one of the sacroiliac joints. Not infrequently it follows a sprain of the lumbosacral joint, strain or other injury of the lumbar joints or back muscles, gluteal myositis or sciatic neuralgia. The pain in sciatic scoliosis is usually of moderate severity except during periods of exacerbation, when it may be intense and disabling. It is usually located over a rather wide area, including the lower part of the back, buttock and thigh on the affected side. It is most intense at the site of the lesion, as, for instance, the sacroiliac or lumbosacral joint. Since the muscles of the back are in a state of constant spasm, all of the spinal motions are restricted and painful. Even motions of the lower limbs, because they bring tension on the pelvic or pelvifemoral muscles, cause pain. The pain in sciatic scoliosis is usually continuous. At times it is relieved by rest in bed; sometimes the patient finds comfort only when sitting; occasionally he may prefer to stand or walk. In this respect this condition is entirely different from the lesions previously considered.

The lesions of which sciatic scoliosis is a symptom are caused by some form of trauma or strain. The injury need not be a severe one and very often it is apparently mild. The point of importance is that any strain, whether mild or intense, may provoke an attack of sciatic scoliosis of any degree of severity.

DERANGEMENT OF THE SACROILIAC JOINTS

There can be no doubt that many people, and especially laborers, suffer from painful lesions of the sacroiliac joints. The common clinical picture seen is that of a patient who after some injury suffers immediate localized pain in one sacroiliac joint. The pain persists for weeks, months or even years and is at times disabling. There is tenderness of variable intensity limited to the affected joint. The chief symptoms are pain in the sacroiliac joint, tenderness over this area and disability. There may be other concomitant symptoms; the motions in the spine, for example, may be restricted because they cause pain in the affected joint. Flexing either lower limb at the hip, with the knee extended, by exerting traction on the pelvis through the hamstring muscles, may be painful. Lateral compression of the pelvis or downward pressure on the iliac bone on the affected side may give discomfort. The chief symptoms, however, upon which we rely for a diagnosis, are localized pain and tenderness.

Röntgen ray pictures are of very little use in this connection. In severe injuries of the pelvis, such as multiple fractures, separation at the symphysis pubis and so forth, actual dislocation of the sacroiliac joint and wide separation of the bones have been seen by most of us. In arthritis of the sacroiliac joints definite changes have frequently been recognized. But in the majority of cases of simple injury to the sacroiliac joint and the adjacent soft parts, the roentgenograms are negative.

As pain and tenderness are subjective symptoms, many and prolonged arguments have arisen, particularly in the medicolegal cases, about the reliability of these symptoms in relation to an exact diagnosis. There is no doubt but that a layman can be educated to appreciate the location of the sacroiliac joints, and may learn this well enough to complain whenever pressure is exerted upon them. But this can be true of only a small percentage of patients, and particularly of laborers, most of whom are ignorant of their anatomy and are in general of low mental caliber. On the other hand we often see cases of sacroiliac derangement in people who do not come under the ruling of the compensation law, and who have no monetary gains to expect from a prolonged illness. If in the course of several examinations, therefore, a patient always points to one sacroiliac joint as the site of his pain, the physician may be reasonably sure that some lesion exists there. If, further, the physician always elicits wincing and complaint when he presses on this area, no matter how thoroughly the patient's attention may be diverted to some other

interest, he may be positive that there is a painful lesion of the sacroiliac joint.

In the cases we are considering it is not always possible to give an exact picture of the pathology and to differentiate the various arthritic and periarthritic, ligamentous and muscle lesions, and hence it is well for the present to use the convenient and inclusive term derangement of the sacroiliac joints. We hope in the future to be able to diagnosticate more sharply than now the different pathological lesions which must at present be included, for the sake of convenience, in the group of derangements.

ARTHRITIS OF THE SPINE

In inflammations of the spine backache is practically a constant symptom. Its distribution depends on the location of the disease and its intensity varies with the severity and nature of the lesion. In destructive lesions such as tuberculosis of the spine, while pain in the back is always present and may at times be distressing, the other symptoms, such as deformity, stiffness, abscesses, general disability and so forth, constitute the important part of the clinical picture.

In the hypertrophic forms of arthritis of the spine backache varies both in its incidence and degree. In the early stages of osteoarthritis and in the final phase when the spine is entirely ankylosed, there may be very little or no backache. In the intermediate period, when the process is progressive, the pain is usually marked. At this time it is present over the entire back, but is most marked in the more movable sections of the spine, namely, the cervical and lumbar regions. The pathological process may be and often is in existence for months and years without any subjective evidence.

This class of case has been the cause of much controversy among physicians and others interested in compensation claimants, for frequently individuals with chronic osteoarthritis of the spine do not suffer any backache or disability until after some injury. The insurance carriers present the argument that the röntgen ray evidence indicates the presence of a disease which antedates the injury and, consequently, the accident is not the proximate cause of the symptoms and disability. On the other hand the patient in many instances has not suffered at all until injured. In such cases it is reasonable to assume, since the claimant has had the lesion of the spine for a long time, even years, without any disturbance or suffering, that, had the accident not occurred, he would have continued to work without any difficulty. And as a matter of experience, we have seen many of these patients incapacitated for variable periods, some even permanently, after an injury. It is not difficult to understand this circumstance as it is readily conceived that an injury may, by strain or tear of ligaments and wrenching of the vertebræ, cause an acute exacerbation and an increase of the chronic inflammatory process in the spine. On the basis of experience, therefore, easily substantiated by a consideration of the physiology of the spine and the pathology of an arthritis, we know that an injury may aggravate an arthritis of the spine and cause disability. This observation is independent of the validity of the contention that chronic osteoarthritis of the spine is probably due to a combination of some systemic or focal infection and a constitutional predisposition.

In typhoid and gonorrheal spondylitis the small joints of the vertebræ and the perivertebral soft tissues are inflamed. The pain is intense and there is marked local tenderness and stiffness of the spine. The backache usually persists for many months and long after the acute stage is past and the individual is about able to attend to a fair proportion of his routine duties. The distribution of the pain depends entirely on the extent of the invasion of the spine.

In none of these arthritic conditions is the pain in the back peculiar, characteristic or diagnostic. The pathology must be diagnosticated through the other symptoms and the objective findings.

In this connection it may not be out of place to bring up the question as to whether injury alone can cause an arthritis, that is, a traumatic nonsuppurative arthritis. We believe it can. We have seen a number of cases in which the back and spine were apparently normal prior to an injury, while following the injury the patient suffered from backache and showed unmistakable signs of an inflammation of the spine. We have a woman under our care at present who had been, as far as we could ascertain, perfectly well up to a year ago, when a weight fell on her back while she was in a stooped position. She fell to the floor. She had immediate severe pain in the back. Seen soon after the injury she appeared to us to be suffering from a contusion and strain of the back. Röntgen ray pictures of the spine were negative. She continued to suffer from pain and disability. At times she would have attacks of excruciating backache. Recently a röntgen ray examination showed that there was haziness and indistinctness of the outline of the articular processes in the lumbar region. Because of the persistence of symptoms a fusion operation was advised. At operation the articular processes were found to be soft, very spongy and evidently diseased. This patient was, therefore, suffering from a lumbar spondylitis which followed and undoubtedly resulted from the alleged injury. It cannot be denied that there may have been some constitutional predisposition, but we have no proof of any such decided and contributing factor, and must accept the injury as the proximate cause of the spondylitis.

MALIGNANT DISEASE OF THE SPINE

In malignant disease of the spine, which may be primary, as sarcoma, or metastatic, as carcinoma, backache is one of the earliest symptoms. It is usually increased during the course of the disease and at times it is so severe that it is difficult to control or to alleviate even with large doses of morphine. The pain is usually limited to the diseased area. The backache is practically continuous; it is increased by motion of the body, but rarely diminished by rest or support. The diagnosis depends not on the severity, location or type of pain, but upon the discovery of a primary focus or tumor, a history of malignancy elsewhere in the body, or clinical evidences of disease of the spine and characteristic röntgen ray findings.

CONGENITAL MALFORMATION OF THE SPINE

It occasionally happens that a patient suffering from backache is discovered to have some congenital anomaly, usually about the lumbosacral joint, such as

an unfused posterior arch of the first sacral segment, an abnormally large or bifid transverse process of the fifth lumbar vertebra, or sacralization of the fifth lumbar on one or both sides. One is inclined to attribute the backache to these congenital lesions. While in some instances such conditions as a large transverse process, may, by friction on the iliac crest, cause pain, it is undoubtedly true that in the majority of cases the congenital lesion has nothing to do with and is not the cause of the backache. We find in reviewing our experience many reasons for this conclusion: First, these malformations have always been in existence for many years, during which time the patient has had no symptoms. Secondly, in the routine examination of patients, congenital anomalous formations or malformations are seen in people who do not suffer from backache. Lastly we have the therapeutic test that in many of those patients who have been operated upon, removal of a socalled cause, such as a large transverse vertebral process, does not give relief. There are, of course, well known conditions, such as cervical ribs, which at times give neuritic symptoms and disturbances of circulation in the upper extremity, and, in isolated and rare instances, a large lumbar transverse process may be responsible for sciatic pain. When there is a well established clinical causel relation between a process of bone and the symptoms, the bony projection should be removed. However, as a general proposition, true in the large majority of cases, the coincidence of backache and a congenital anomaly does not indicate that the congenital bony malformation is responsible for the pain.

STRAIN OF THE BACK

This condition may be either acute or chronic. In both varieties are included strain of, and damage to, the muscles of the back and the intervertebral and costovertebral ligaments. The injury may be limited to a stretching of these tissues, or it may consist of a stretching of some and a tear of other fibres of the muscles and ligaments.

A strain of the back may involve only a few tissues and a small part of the back, such as the lumbosacral junction; it may be present in several areas simultaneously, or it may extend over a large section of the back, such as the musculature in the dorsal and lumbar regions. Strain of the back occurs most often in the lumbar area, because during ordinary activities, particularly those of the laboring class, the lumbar muscles and ligaments are subjected to greater and more frequent use than those in the cervical or dorsal sections.

In an acute strain the individual experiences a sudden sharp pain in the back. This persists and is aggravated by all motions of the body including respiration. There may be one or more tender areas and in an occasional case some discoloration. There is some stiffness of the back and the patient is inclined to guard against unnecessary motions of his body. A röntgenogram of the back is negative in that it shows no osseous lesion. Usually the pain lasts a short time, varying from a few hours to a few days, and disappears completely, leaving no ill effects. A strain of the back may be particularly painful, last longer than the ordinary acute attack or become chronic when it is superimposed on a preexisting chronic lesion, such as osteoarthritis of the spine, rigid posterior curvature of the spine or scoliosis.

Chronic strain of the back may result from a single acute attack, a succession of acute attacks or from a simple injury of a previously inflamed or deformed spine. The chief symptoms are persistent pain and weakness of the back, and very often localized tenderness. It is difficult to diagnose this lesion with certainty, because practically all of the symptoms are subjective and the surgeon must rely on the patient's statements. Since only the soft tissues are affected the röntgen ray offers no assistance. The diagnosis is ordinarily questioned only in compensation and other medicolegal cases. Each case must, therefore, be studied sympathetically, diagnosed individually, and it should be frankly admitted that, in denying the existence of a chronic strain of the back, we may often be in error. In our opinion the best method to pursue in arriving at an accurate opinion in cases in which there is some doubt about the patient's veracity is the one adopted by the New York State Labor Department. The claimant is placed in a hospital for a week or more for observation. There, under the constant supervision of the attending physician, the house officers and the nurses, the patient may be observed and studied when he is, so to speak, off his guard, and the true state of affairs may be discovered. Numerous telling measures may be adopted to reveal the condition and functional capacity of the patient's back and the reliability of his statements. The most dependable symptoms are persistent localized discomfort in the back on bending the body and persistent localized tenderness. When we can assure ourselves that these symptoms are present, we need have no hesitancy in asserting the existence of a chronic strain of the back.

FRACTURE OF THE RIBS

Backache and pain in the chest in cases of fractured ribs are located at the site of injury. In an ordinary uncomplicated case the pain is sharp and intense for a week or ten days after the accident. The pain is increased by motion of the body and especially by deep breathing. Rest, secured by such measures as strapping the chest and restricting the respiratory excursions, relieves the pain materially. Gradually the pain subsides and at the end of about three weeks the patient is practically well. In laborers the pain and disability are greatly prolonged. This may obtain even if the fragments are in perfect alignment. We have seen instances in which the discomfort and tenderness persisted for months, long after it was possible to demonstrate any pathological changes.

In summing up this study of backache, we would emphasize the importance of arriving at an exact diagnosis of the pathology. With due consideration to the nature of the injury or onset of the trouble, the course of the symptoms, the intensity, duration, distribution and character of the pain, the associated symptomatology and the laboratory findings, one should be able, in the vast majority of cases, to diagnosticate the lesion accurately. It should further be remembered that all symptoms of an injury in a laborer tend to be prolonged, and hence one must be patient and sympathetic in applying what sometimes appears to be unduly long treatment.

1 West Eighty-fifth Street.

Practical Therapeutics

The Efficiency of Strophanthine Sublingually Administered

JAMES L. TRACY, M.D.
Toledo, Ohio

More has been written about the pharmacology and therapeutics of the digitalis bodies on one day, only to be unwritten the next, than has been the case with any other dozen drugs all put together; with the possible exception of alcohol.

CASE.—A man of German ancestry, aged sixty-three, six feet three inches tall, weighing 291 pounds, of heavy bony and muscular frame. Until four years ago he had been a hard worker of various kinds of manual labor. An injury to his thigh, at that time, put him in bed for about three months, and after the cast was finally removed, he was only able to walk around in his home and, occasionally, on the street for short distances. During all of the four years the injured limb had been kept in bandages and for the last year the other limb had also been bandaged.

For a week before I first saw him he had been suffering from an influenzal cough. Influenza was then epidemic. For three days the cough had been very violent and dry. In coughing he had made full use of his powerful muscles. After three days profuse bronchial secretion set up, and at the time of my first visit he was expectorating two or three quarts of mucus during the twenty-four hours.

He was sitting, propped up with pillows, on his couch. He could not lie down. He was breathing little short breaths, about sixty a minute. He could speak only in short monosyllables, and then only after two or three preparatory respirations. His color was neither pale nor cyanotic, but on the contrary was of more than normal purple color. The tissues of his face and hands, as well as all over the body, felt hard to the touch, almost boardlike. At no place was there pitting on pressure. The hands could not be closed. The feet were three times their normal size. Legs were as full as the skin would hold. Large blebs formed over the ankles.

The chest walls were more than two inches thick. The abdominal walls were so distended that I thought the peritoneal cavity was full. A surgeon concurred; but his four inch trocar pressed in to full length, and more, tapped only waterlogged tissues. The penis and scrotum were not at all affected, the only edema exempt parts of the whole body. No radial pulse could be felt through the edematous parts. No heart sounds could be heard. For a short space, over the carotids, pulsation could be felt, which was regular, and about 120. Of course, no respiratory murmur could be heard, and while in the act of coughing only the very coarse râles could be heard, but, over a space about six inches in diameter, over the heart region, there was a squeaking noise which tallied with the carotid pulsations. Evidently an emphysema had formed, in the region of the heart.

He was voiding about twenty-two ounces of urine during the twenty-four hours, specific gravity .20, acid, no casts, no cells, no albumin, no bile. Hemoglobin was about 80. Bowels were moving regularly. He was very nervous and easily thrown out of mental balance. A continued noise, such as the ticking of a clock, increased the dyspnea. Strangely enough, he had appetite and was managing to eat as much as he needed.

Except for the coughing and the consequent dyspnea which made it impossible for him to lie down, either night or day, his general physical condition was not different from what it had been for many months. The very evident need of elimination, from some place, suggested that the expectoration—even if it were possible to check it—had best be let alone.

There was no possible way of finding out the heart's condition, but guided by general principles, one one hundredth grain of strophanthine dissolved in a single drop of water was placed under the tongue with a medicine dropper. Within five minutes—in all of the tumult—there was noticeable a little easing up of the fear of a not far distant death. This dose was to be repeated every two hours for a half dozen times, then given every four hours. Magnesium sulphate was to be given to produce watery passages. Strychnine one thirtieth grain every four hours was also given. Twenty-four hours afterwards, the radial pulse could be detected. The salts had acted. The strophanthine had not at all troubled the patient, so the dose was made one sixtieth grain, every four hours.

The influenza ran the usual course, and subsided. Gradually it became possible to study the heart and lungs. There were found mitral and aortic murmurs which probably had been of long duration. Eventually, though, the valve defects might have caused the dropsy. Quite likely this was the case. The heart seemed to be somewhat enlarged. The lungs were everywhere normal.

The giving of strophanthine in this dose—one sixtieth grain three or four times a day—has now been kept up for four months. The urine is much increased in amount. The patient weighs thirty-five pounds less. He sleeps in his bed all night, and in the morning his feet are free from swelling; by night, however, they are again swollen. It takes but little exertion to cause shortness of breath. The thigh injury will never be recovered from. He will probably have to take strophanthine as long as he lives. Two small uncoated tablets dissolved in a drop of water and put in the mouth make medication easy.

One may have good authority for a different opinion each day as to just how strophanthine controls the heart. In this case the cardiac centres had probably for years been at work according to biological order, trying to adjust the dysfunctioning heart valves, to the best interests of the body as a whole. Naturally the functioning of biology is always towards the defeat of biology. The anasarcous condition was nearing the biological finish. Strophanthine

under the tongue came in direct contact with efferent nerve endings. It produced nerve impulse and was carried to sympathetic cardiac centres. The strophanthinized centre thus got in deeper than was the biological inhibition centre. The accelerator impulse, from the strophanthine dictated centre, again vitalized and nourished the fibre of the heart muscle. The metabolic makeup of that muscle fibre nourishment is beyond laboratory demonstration. Evidently in this case a strophanthine glucoside did not bathe the fibre. The fibre action was too prompt.

A New, Nontoxic Analgesic and Antirheumatic Drug of Definite Value in Vascular Hypertension

EMANUEL W. LIPSCHUTZ, M.D.

Brooklyn

(*Concluded from page 278*)

Because of the limitations of space, the entire group of thirty-six case histories will not be cited. The following six protocols have been selected as typically representing the therapeutic action of the drug.

Case I.—B. F., female, married, housewife, aged forty-two, had an attack of acute tonsillitis, lasting four days. For three days following the throat infection, she felt pretty well; but, on the morning of the fourth, she experienced severe painful stiffness in both thighs, which was aggravated when she attempted to straighten out her legs. There was also stiffness in both wrists, and attempts to flex or extend the hands caused severe pain. At this time, the patient took atophan of her own accord; but, in spite of this medication, her condition became worse. The wrists showed red, inflammatory areas along the extensor tendons; the right knee and ankle were extremely painful and tender over the tendon sheaths, showing sensitive red patches over these areas; and stiffness and pain in the muscles of the thighs persisted.

At this stage, the patient sought medical advice. When I saw her on April 8, 1926, she was prostrated and confined to bed. The temperature was 101° F. I ordered a milk diet and an analgesic mixture. Blood culture and uric acid estimation were found negative (Dr. Bleivass).

Five days later, the patient remained unimproved. In fact, the left knee and ankle joints were now involved and showed red patches over their tendon sheaths, and there was a large red patch over the gluteal region. The diagnosis was acute rheumatic infection with polytenosynovitis, probably secondary to acute septic tonsillitis.

At this stage, expuralgin was prescribed in doses of ten grains (0.65 gm.) every three hours. On April 14th, after the administration of only five doses, there was great relief in the thigh muscles and ankles and the patient was able to leave her bed for a period of about four hours. However, getting up appeared to aggravate her condition; for she had a return of symptoms, although in a milder form. Expuralgin was then administered continuously up to April 24th, and the patient made an uneventful recovery. The red, inflammatory patches showed gradual retrogression with the pain and tenderness in the joints and tendons. It is interesting to note that during the administration of the drug, diuresis was increased to a considerable degree. The patient at no time complained of gastric disturbances.

Case II.—M. G., male, aged thirty-nine, was taken ill in December, 1925, with a subacute rheumatic infection involving both angle joints and the right shoulder. He was confined to bed for a period of three weeks, after which he began to suffer from a constant pain in both arms, extending about half way down the forearms. Physical examination disclosed nothing of importance except a moderate degree of oral sepsis. The pain, as described by the patient, corresponded to the distribution of the musculospiral, radial, and ulnar nerves. The diagnosis was neuritis, probably resulting from focal infection in the mouth.

Dental supervision was advised. Expuralgin was administered in a dose of eight grains (0.52 gm.) three times a day. After one week of this medication the patient reported complete relief from pain. He was able to flex and extend his forearms with perfect freedom. Four weeks after the discontinuance of medication, he was still free from pain and disability.

Case III.—B. W., female, married, housewife, aged thirty, complained of pain, drawing and lancinating in character, along the course of the left musculospiral nerve, and also of a vague drawing pain in the muscles of the lower part of the back on the right side. These symptoms lasted for two weeks and did not respond favorably to hot applications and other household remedies.

Physical examination revealed nothing of importance. A diagnosis of neuritis was made.

Expuralgin was given in doses of ten grains (0.65 gm.) every three hours. There was complete relief of all symptoms after six doses. Eight days after the discontinuance of medication the patient was still free from symptoms.

Case IV.—H. F., female, married, housewife, aged fifty-two, had an acute coryza lasting several days. This was followed by pain in the region of both antra. Several days later the pain disappeared from the right antrum and remained localized in the left. There was a severe, shooting, paroxysmal pain on the entire left side of the face and scalp. The attacks came at intervals of about one half hour. The patient took aspirin in doses of five to ten grains (0.324-0.65 gm.), but was not relieved. She came

to me on the third day of her illness. Expuralgin was given in doses of five grains (0.32 gm.) every three hours for a period of two days, but there was no appreciable relief at first. Then the dose was increased to eight grains (0.52 gm.) every three hours, and there was complete relief of the symptoms within two days.

Case V.—D. L., female, married, housewife, aged fifty-six, came for examination on April 24, 1926, complaining of pain in both knee joints and the sacral region. The pain was constant and more pronounced in cold, rainy weather. Cholecystectomy had been performed in July, 1925, and all the teeth extracted in September of the same year. The present illness dated back to September, 1925. Since that time the patient had been taking various therapeutic agents, including coal tar products, endocrine preparations, and remedies directed toward the alimentary tract; but these measures gave very little relief. Iodides and salicylates were administered intravenously; but, while this treatment afforded relief, it had to be abandoned because it gave rise to severe diarrhea.

On April 24th, because of a return of symptoms, expuralgin medication was begun, ten grains (0.65 gm.) three times a day. On May 4th the patient reported that she had felt well for the last ten days under this medication. From that time on five grain (0.324 gm.) doses three times a day were advised. On May 21st the patient stated that she was free from pain. While it is impossible to predict how long the relief from symptoms will last in this case, it is evident that the drug brought about definite abatement of the symptoms without causing any appreciable ill effects; therefore, in case of recurrence of symptoms, a return to expuralgin medication would be warranted.

Case VI.—M. T., female, married, housewife, aged forty-seven, complained of inability to raise her right arm because of severe pain in the shoulder joint or to flex or extend her forearm because of excruciating pain in this region. The illness began four days previously, at which time she felt pain over the olecranon process. At that time attempts at flexion or extension of the forearm met with only slight difficulty. The condition became progressively worse.

On examination, the right arm was in a position midway between flexion and extension and held closely to the side of the body. Because of excruciating pain, the patient was unable to abduct her forearm. There was marked tenderness in the regions of the right shoulder and elbow joints and along the course of the musculospiral nerve. Otherwise, physical examination was negative. The diagnosis was acute neuritis and probably myositis, rheumatic in nature. Expuralgin was given in doses of ten grains (0.65 gm.) every three hours until the acute pain subsided, then every four hours. On the fourth day the patient was so much better that she was able to comb her hair without assistance. Altogether, the period of medication lasted eight days, at the close of which period the patient was entirely free from symptoms. She has remained so to date.

CONCLUSIONS

1. Expuralgin (potassium magnesium acetyl citrate) is not toxic to rabbits when administered intramuscularly in three and a half times the therapeutic dose by mouth.

2. Careful observations showed no depressant action of the drug on human subjects, and there was no gastric disturbances following its use.

3. Expuralgin induces a definite artificial leucocytosis. This factor probably explains much of the value of the drug in local inflammatory conditions.

4. The drug promotes the elimination of uric acid and increases diuresis.

5. Expuralgin has definite analgesic effects in painful affections.

6. In vascular hypertension, expuralgin produces pronounced and prolonged reduction of the blood pressure. When the hypertension is due to arteriosclerosis, however, the effects are unfavorable.

7. Clinical cases are cited to illustrate the therapeutic efficacy in rheumatic, arthritic, neuritic, and other painful conditions.

8. Expuralgin is indicated in the treatment of high blood pressure, articular rheumatism, arthritis deformans, rheumatoid affections, rheumatic myositis, polytenosynovitis, neuritis, and migraine. It is contraindicated in arteriosclerosis.

9. The dose of expuralgin used in the cases here reported was ten grains every three hours until pain abated, then ten grains three times a day until lasting relief was obtained.

Simplified Method of Filling Pulmonary Cavities.—Arnold Josefson (*Schweizerische medizinische Wochenschrift,* March 20, 1926) proposes the use of a hollow spatula, through which lipiodol (iodized oil) may be injected without the aid of direct ocular laryngeal control. If the patient is placed in a Trendelenburg position immediately after the injection, the oil can be made to flow toward the upper lobe, and by changing the position into a lateral one the oil may be directed in any desired direction. Almost the entire amount of the oil may occasionally be caused to lie in the upper portions of the lung, and even near the surface of the lung.

In order that the injection should reach the lung it is absolutely necessary that the rima glottidis should be wide open on marked traction of the tongue. The technic of the injection is as follows: The pharynx and especially the dorsum of the tongue must be well cocainized. The tongue is then drawn outward with force. The hollow spatula is then applied to the back of the tongue and the patient is instructed to breathe deeply. With every inspiration the lipiodol is injected. The patient is then placed in any desired position and immediately röntgenographed. As a rule, twenty to thirty c. c. of the oil is sufficient. With good anesthesia there is rarely an irritative cough.

The Endocrine Glands as Dominant Factors in the Therapeutic Action of Light and Heat*

CHARLES E. de M. SAJOUS, M.D., Sc.D., LL.D.

Philadelphia

Although the physiological action of heat in any of its therapeutic forms cannot be interpreted without taking the functions of the ductless glands into account, no set of organs is perhaps more neglected than they are in the study of this important question. The cause of this neglect is not difficult to discern: it is the perpetuation of obscurity concerning the functions of these organs by textbooks of physiology and books on endocrinology, which though replete with organotherapeutic advice, take no pains whatever to explain the mode of action of the organic products used, thus persistently keeping up the empirical methods which this society has always opposed. The excuse that this neglect of the pharmacodynamic side of endocrinotherapy is inevitable because the physiological rôle of the endocrine organs is unknown is invalid, for it is due only to the fact that the writers of such material have merely followed the physiological bell-wether which has to this day led them to a sterile *terra incognita*. The fact that despite the vast amount of painstaking and extremely valuable labor devoted to the subject by physiologists ever since the middle of the last century (when the term internal secretions was introduced) the true rôle of these agents in the body is still unknown to them, clearly suggests that something wrong has obscured their vision.

I have long urged the reason for this, and submitted in 1903 deductions concerning the functions of the various endocrine organs which differed totally from those from time to time proposed, then sidetracked, by physiologists. This was due to the fact that our methods of research were dissimilar. While physiologists depended mainly on their own branch for data, my labors covered, besides physiology, the other branches of medicine, both clinical and auxiliary —a method now termed "synthesis of sciences." No conclusion was reached until all these branches had contributed their findings, and any conclusion postulated represented the apex of a pyramid composed of all this aggregate knowledge.

*Read before the American Therapeutic Society, Philadelphia, June 11, 1926.

Time has sustained the value of this method. While the physiologists have revealed not a single fundamental function for any endocrine organ, the principles of the functions I laid down in 1903 and 1907 in the first book ever published on the internal secretions, have all held their own. Even the pituitary body has been forced by events to lapse into the line of thought I pointed out over twenty years ago. What did the lesions practised by Camus and Roussy in 1913 and many others since, above and behind the pituitary body, producing effects ascribed to a supposititious internal secretion of that organ, do but prove that my views of 1907 concerning its functions were the ones that were sound? All the lesions were in basal nuclear areas and nerve paths that I had described.

Time and the scientific loyalty of many investigators is beginning, however, to prove once more the strength of patience or forbearance. The question treated in this paper bears mainly upon tissue oxidation and thermogenesis as dominant functions of the adrenals (1). One of our distinguished physiologists, Dr. F. S. Hammett, of the Wistar Institute, stated at the meeting of the Association for the Study of the Internal Secretions last year, that he had devoted two years to the study of the functions of the adrenals, and that he had reached the conclusion that I had not erred when I attributed to the adrenals so dominating a position in the body. Dr. George Crile also declared at the Congress of Anesthetists last year, that the labors of physiologists and of investigators in other lines had only served, in recent years, to confirm my views and that even physiologists were beginning to admit it. I mention these various facts only to show you that I am standing on firm ground on the question in point.

What I am about to tell you, however, has a far greater reach than the important therapeutic method which is described in the heading of this paper, for it entails the solution of a problem which in importance is as great as the discovery of the circulation of the blood which we owe to Harvey. An editorial writer in the *Journal of the American Medical*

Association rightly declared in 1919 that "an answer to the question as to how the all important oxidations in the body are brought about is almost as obscure as it was a hundred years ago." Indeed, even in the 1924 edition of his textbook of physiology (page 392), Howell states that "the respiratory history of oxygen ceases after this element reaches the tissues." In truth, little progress has been made in this direction beyond the fact that oxidations occur in the tissue cells ever since the discovery of oxygen by Lavoisier in 1780.

The consequences of this state of things—distressing beyond expression—are well summarized in Professor Halliburton's statement of 1921 that "our knowledge of tissue respiration is so scant that we can say but little of its pathological bearing." Deplorable also in this connection is the fact that even the most elementary manifestations of disease met constantly in practice have remained unexplained, the ubiquitous process of fever for instance. "Even if we grant," wrote Lazarus Barlow over twenty years ago, "that fever is beneficial, we are completely ignorant of the manner in which it acts." The same ignorance prevails to this day. A multitude of valuable data but no solution. With the dangers of hyperthermia, hemolysis and autolysis before him the family doctor suffers the tortures of the damned, lest by trying to save through fever, he kill by fostering it!

The profession at large and laboratory men in particular should realize that medicine is not suffering today for lack of data but from the perpetuation of obscurity through neglect of what is available. As the late Sir James Mackenzie wrote but five years ago: "The conception of medical research which is dominant today is so immature and imperfect that it renders fruitless much of the research work. Indeed, so imperfect is the conception that fields essential to medical progress are not recognized." This applies particularly in the present connection, for if the physiologists and pathologists had left their avowedly sterile paths to consider the newer aspect of pulmonary and tissue respiration I opened in 1903 with the adrenals as main factors, tremendous advances would have been made in all directions during the last two decades, with a correspondingly great saving of human lives as the result.

In its relations to our subject, i. e., the curative properties of heat and light, the problem of tissue respiration is paramount, for both are intimately bound up with the process of fever, an exacerbation of this function as I have described it. In other words, these therapeutic measures, however applied, merely enhance Nature's own defensive activities by producing an artificial local or diffuse febrile process. What is the nature of this process?

In the brief time at my disposal I can only submit the deductions reached, referring you for the evidence to previous writings.[1]

Fever is primarily due to excessive activity of the adrenals, as regards the supply of agents which carry on heat production in the tissues. These agents are three in number: the medullary secretion which I termed in 1907 *adrenoxin,* and the products of the adrenal cortex *lecithin* a phospholipoid, and *cholesterol* a monatomic alcohol. The red blood corpuscles, in which these three bodies are also found besides their hemoglobin, appropriate them on passing through the adrenals, then take up oxygen on passing through the lungs, thus converting their adrenoxin into adrenoxidase, i. e., their hemoglobin in oxyhemoglobin. Thus charged the red corpuscles are transported by the bloodstream to the tissues, in the pericellular spaces of which they discharge a part of their contents in the form of blood platelets. In the tissue cells they meet two main substances: enzymes and food products of various kinds.

Taking into account only the main participants in the intracellular vital process the latter is as follows: The adrenoxidase, which is the oxygen carrier, reacting with the phosphorus of the lecithin, liberates heat energy. As enzymes are active up to a certain limit, according to the temperature to which they are subjected, the cell enzymes, trypsin, lipase, etc., then split the proteins, fats, sugars, etc., also present in the cell. We do not have "tissue oxidation" as is now taught, but the liberation of heat to promote activity of the enzymes which sustains the whole process of metabolism, both its anabolic and catabolic phases.

Yet, how is this process activated or held in check to insure a just mean of heat liberation, that represented by the normal temperature? The thyroid secretion is the activator while the cholesterol, previously referred to, is the inhibitor.

While the action of cholesterol is given as unknown in textbooks and regarded as an antitoxin by some, considerable evidence, for which I must refer you to my recently published article in *Endocrinology,* is available to show that it inhibits the thermogenic activity of lecithin which it accompanies in all tissues, even in the red corpuscles. Hence its recognized value in secondary anemias, cancer and other disorders in which hemolysis occurs. Cholesterol is the brake, so to say, of the thermogenic action of lecithin.

As to the process through which the thyroid secretion produces the reverse effect, that is to say, acts as a lecithin activator, Kendall, referring to his thyroxin, states that the manner in which it acts in the tissues is unknown; but he is swerved away from the true explanation by his conclusion that thyroxin which, he says, "is active in nearly all the cells of the body," is a catalytic agent. As I held twenty years ago, the thyroid hormone is bound up with an oxidizing enzyme (my adrenoxidase) which is itself a catalytic agent. Hence the term I then applied to the thyroid secretion "thyroiodase." But the physiological rôle of this hormone is not that of catalysis, which, in fact, plays the rôle of activator in many other enzymic functions. As Reid Hunt said in this connection, "the mode of action of iodine in thyroid is unknown."

In truth, the action of the thyroid hormone or principle could not be worked out without knowing the rôle of lecithin in the tissues, another admittedly unknown feature. In 1903 and in 1907, I pointed out that it was by enhancing the sensitiveness of the phosphorus in all tissues that the iodine of the thyroid increased metabolism. Four years ago I found that the main cellular substance thus acted upon was the phospholipoid lecithin which it activates by sensitizing, or increasing the lability of, the phosphorus which this lipoid contains.

[1]See either of the ten editions of my work on the "Internal Secretions and the Principles of Medicine" 1903 to 1922, and particularly my article in *Endocrinology,* November-December, 1925, pages 441 to 455.

Hence the fact that in exophthalmic goitre or hyperthyroidism the metabolic rate, the pulse, the appetite and emaciation progress as concomitant symptoms. The iodine in organic combination, containing the catalytic agent of adrenal origin, being produced in excess, the lecithin, the heat liberating agent, is oxidized in proportion.

The tissue enzymes being rendered correspondingly active, the fats, proteins, etc., are consumed in proportion.

The beneficial effects of heat or light therapy in any of its forms, including heliotherapy and to a certain extent the röntgen rays, are due to their influence upon this physiological process. They fulfill the rôle carried out by the reaction between the adrenoxin —oxygen and the lecithin, which serves to liberate heat energy. This heat energy, by raising the proteolytic activity of enzymes also present in the tissue cells, enables them to break down or digest pathogenic germs, their toxins or toxic waste products of metabolism and thus to antagonize the diseases any of them may produce.

Heat or light therapy thus provokes an artificial local fever, emulating thereby Nature's own way of counteracting infection. Excessive fever (hyperpyrexia) as represented by a body temperature exceeding 105° F. is harmful, however, by endowing the proteolytic cellular enzymes (trypsin) with excessive digestive activity. The blood cells and even the tissues may thus be themselves digested (hemolysis or autolysis), causing either profound anemia, valvular diseases of the heart, endocarditis, arthritis, or other disorders and even death. The therapeutic use of heat or light radiation are similarly beneficial up to a certain limit but harmful when carried beyond it.

Status Lymphaticus*

R. S. LEADINGHAM, M.D.
Emory University, Ga.

The progress of tissue growth and development is guided from the undifferentiated layers of the embryo toward completion of design and correlated function, not only by the power of heredity and the influences of environment, but by certain stimulating, restraining, and correlating forces within the developing structures themselves. Of these, the specialized functions of such tissues as the central nervous system, the ductless glands, and the reticuloendothelial system; the distribution of nutriment; and the mechanical effect of tissue tension, represent some of the influences that combine to maintain normalcy in tissue growth throughout the life of the individual. These factors probably constitute a large part of the mechanism that governs the balance of cellular capacity for work and reproduction, and they have also been called upon to explain the presence of anatomical anomalies and the nature of neoplastic growths.

Of late years considerable has been added to our knowledge concerning these factors, but their interrelationship and the manner in which the individual emphasis varies according to the stage of development and needs of the body, offer a wide field for investigation.

It is known, for example, that the cellular elements of the blood are formed in the embryo by structures that later relinquish this function to a comparatively small portion of the bone marrow and lymphoid tissue. These centres are capable throughout life of varying their output, supplying in such accidents as hemorrhage and infection the increase required. When the need is met and the organism's well being restored, they return to a production just sufficient to maintain the *status quo.*

In the blood dyscrasias, as polycythemia and the leucemias, there is an uncoordinated effort on the part of the hematopoietic system, caused by either an undue stimulation or release of inhibitory influences, that results in vicarious activity which seems to include all the potentialities of the blood forming tissues. This activity is characterized not only by an increase in the number of cells in the blood stream, but also by the presence of more or less undifferentiated types of varying degrees of immaturity. Other tissues of the body are capable of behaving in like manner, as malignant new growths, which, without prompt measures for removal, will proceed with their proliferation and metastasis until the organism is destroyed.

In both of these instances there is represented a misguided or undirected effort on the part of an individual cellular element which calls upon the host for its support at the expense of other tissue's well being. Both suggest not only a potential trend toward bolshevism, but a breaking down of a mechanism that normally holds it in restraint.

In childhood, the lymphoid tissues form a barrier to many infections. The mesenteric lymph nodes especially seem to have an important part in protecting the child from harmful invasions until a degree of immunity is established. Then, as the years pass, these structures occupy relatively less prominent places, anatomically, at least, and in the adult they are commonly smaller than they were in the child.

Sometimes the development of this tissue persists or increases out of all proportion to its usefulness. Such an increase may be represented by local manifestations as hypertrophied tonsils and excessively developed adenoid tissue in the mesopharynx; or it may be a part of a symptom complex in which there is persistence and enlargement of the thymus gland.

*Read before the Fulton County Medical Society, Atlanta, Georgia, February, 1926.

This latter state is known clinically as status lymphaticus, and individuals so afflicted commonly show, with evidences of lymphatic hyperplasia, indications of abnormalities and feebleness of other tissue development that may persist through life. The process differs from neoplastic development in that the cellular elements show no inclination toward autonomous

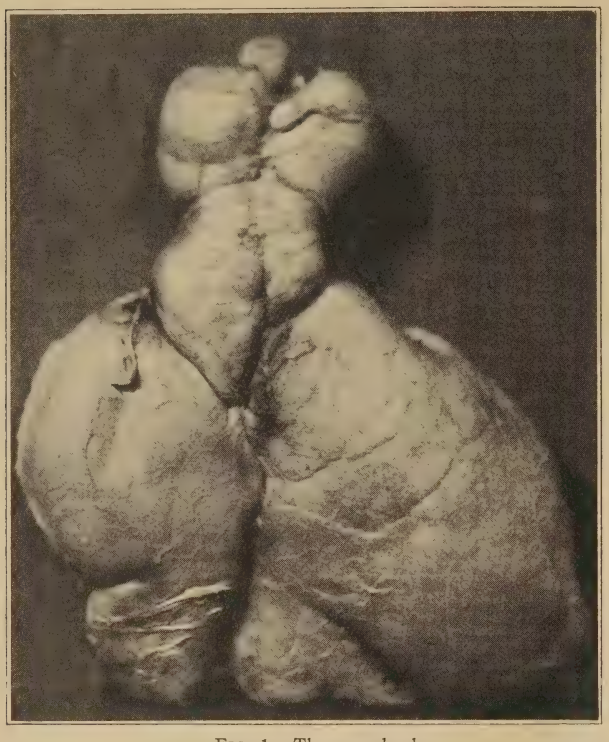

Fig. 1.—Thymus gland.

growth. It is unlike that found in blood dyscrasias, in that there is no evidence of the tissue's activity in the blood stream other than sometimes a relative lymphocytosis. Like both of these conditions, however, it represents a development of a specialized tissue at the expense of the whole.

PHYSIOLOGY OF THYMUS GLAND

The significance of the enlarged thymus in status lymphaticus could be more profitably discussed if we knew more of its normal function. Its probable relationship to the thyroid, the anterior lobe of the pituitary, the medulla of the adrenals, and the sex glands, has been the subject of much interesting speculation. The fact that the experimental laboratory has failed thus far to isolate a thymic hormone is, of course, no proof that it does not exist. Butchers are said to have noted that the thymus in the castrated bullock is nearly twice the size of the gland in a bull. Basch, Klose, Vogt, and Matti conducted experiments that were for a long time accepted as proof that removal of the gland interfered with bony development. Park and McClure (1), however, demonstrated that the normal laboratory animals, kept in the same quarters and on the same diet, showed like results of their confinement.

The cortical portion of the normal gland is composed of a reticulum in which are held small round cells, the nature of which were for a time disputed, but are now generally recognized as small lymphocytes. After childhood these are lost and the gland decreases in size until its remains are buried in a mass of fat that develops in its interstitial tissue.

In status lymphaticus, the lymphoid hyperplasia in the cortex of the thymus is comparable to that found in other lymph adenomatous structures. The normal appearance is altered by an increase in the number and size of the germinal follicles, and by the lymphocytes filling the sinuses. Attention has been called by some writers to necrosis of the centres of the lymph follicles, hypoplasia of the cardiovascular system and changes in the thyroid and adrenals; but these changes have not been universally observed.

CLINICAL PICTURE OF STATUS LYMPHATICUS

The clinical picture in children suffering from status lymphaticus suggests either the angelic child of delicate coloring and mold, or the mentally sluggish and coarser featured individual, both of fine skin and shapely limbs. They are especially susceptible to intercurrent infections and often fall victims to tuberculosis. Enlarged tonsils and adenoid vegeta-

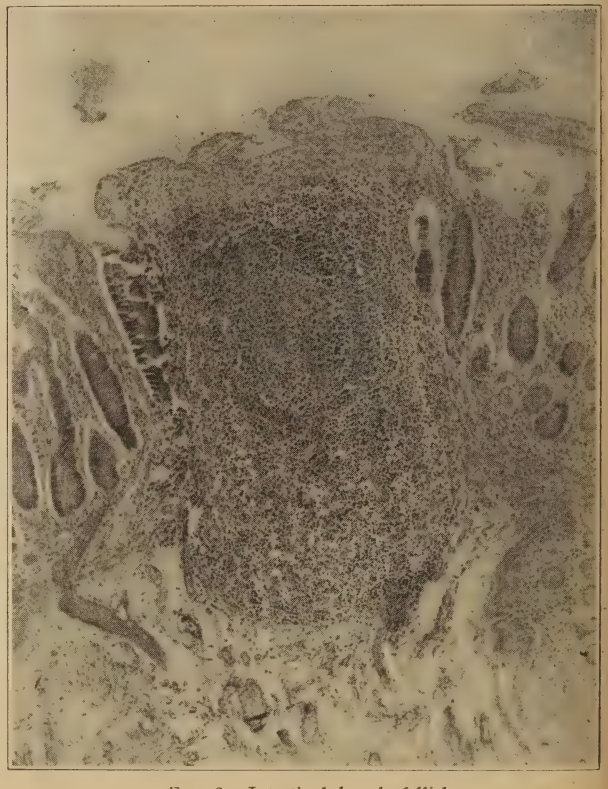

Fig. 2.—Intestinal lymph follicle

tion in the nasopharynx are common and an apparent increase in the number of follicles at the base of the tongue has also been noted. Recurrent asthmatic attacks and laryngeal spasms are classical symptoms of the disorder.

In adults, the male is inclined to show skin of a delicate texture, a well rounded and proportioned body, underdevelopment of the genitalia, and scanty hair on face and body. In the female there is likewise an unusual delicate texture of the skin, an accentuation of the graceful outline of the body, and scanty growth of axillary hair. They are noted to be subject to various forms of nervous exhaustion and even grave mental disease. Emerson

(2), from among one thousand patients suffering from the effects of attempted suicide, drug, and alcoholic addiction, found 220, or twenty-two per cent., that he thought showed most or all of the evidences of status lymphaticus. Bartels and Miloslavich (3) found that 80.5 per cent. of 232 cases of suicide showed, at autopsy, signs of this stigma.

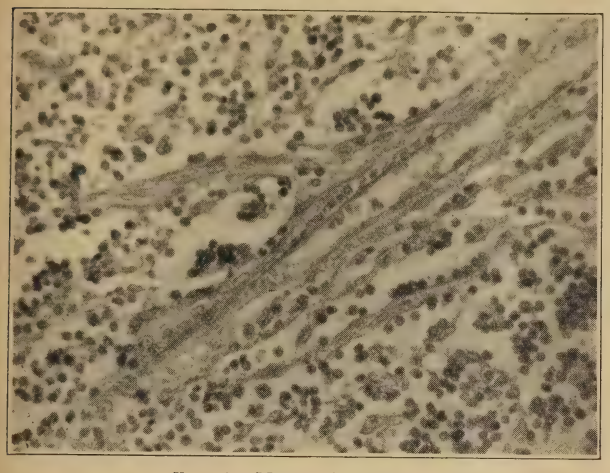

FIG. 3.—Mesenteric lymph node

The tragedy of status lymphaticus, however, is not in these rather ill defined abnormalities, but in the sudden death that frequently overtakes its victims. A short time ago I was called to visit a home where such a tragedy had occurred. In this instance the victim was a five year old boy, who had, from his birth, been subject to attacks of difficult breathing and laryngeal spasm. He had also never learned to talk. The evening before, he complained of trouble in his throat, and his mother applied some external medication and tied a piece of flannel about his neck. At one o'clock in the morning he rose up in bed, choking, and awoke his mother. She caught him up, put him in a chair, and ran to the medicine cabinet for a dose of ipecac, which had, in previous attacks, always brought relief. Returning, she raised the spoon to his lips, and as she did so he gasped and fell dead in her arms.

Autopsy revealed a well developed child, showing no abnormality except a thymus weighing thirty-two grams, greatly enlarged mesenteric glands, and prominent follicles in the gut. Microscopical examination showed evidence of increased activity in all the lymphoid tissues, lymph glands, spleen, follicles of the gut, and cortex of the thymus. There seemed to be, besides an increased number of germinal centres, a decided proliferation of the reticular cells in the surrounding stroma.

As in this case, death may occur without any apparent cause, or may follow the most trivial injury. It has taken place in the operating room as an unfortunate incident in the course of a general anesthetic.

CAUSE OF DEATH

It has been variously suggested that such deaths may be due to abnormal pressure of the enlarged thymus, a toxic agent secreted by the gland, or to a state of anaphylaxis in which the whole lymph adenomatous tissue is involved. Those favoring the toxic theory believe that the toxine is responsible for the asthmatic attacks, and is also capable of causing heart failure. So far, none of these theories have been proven experimentally.

CONCLUSIONS

In conclusion, we must note, that, although for a long time status lymphaticus has been recognized as

FIG. 4.—Spleen

a clinical entity, and, in spite of the interesting experimental work that has been, and is being done, we know nothing of its cause. We look to the laboratory for further information concerning the interrelationship of lymphoid and thymic development with the secretions of the ductless glands; and the importance of increasing our knowledge of a condition fraught with such grave potentialities should stimulate us, not only to make a close clinical investigation of suspected cases, but to secure postmortem examinations in all cases of sudden death.

Nondiabetic Glycosuria.—H. J. John says (*Endocrinology,* March-April, 1926, vol. 10, page 115) a diagnosis of diabetes should never be based on the presence of glycosuria alone. A glucose tolerance test may be made by taking a sample of fasting blood, then giving to the patient an icecold solution of one hundred grams of glucose dissolved in three hundred cubic centimetres of water flavored with the juice of a lemon. Samples of blood and urine taken at periods of half an hour, one hour, and two, three, and four hours, if the patient is diabetic, will show a slow and prolonged rise of the blood sugar curve, with an equally prolonged fall, while in a nondiabetic the curve will rise quickly with an abrupt fall. Examples are given of cases of diabetes of renal origin correctly diagnosed by this means. Observation shows nondiabetic glycosuria to be an innocent anomaly requiring no restriction of diet or other treatment.

On Endocrine Diseases*

JOHN WILLIAM SHUMAN, M.D., F.A.C.P.
Los Angeles
Associate Professor of Medicine, College of Medical Evangelists

Much medical fiction has been written about dreams and endocrines. Some wit has called the ductless glands—"the glands with an eternal secretion." A few facts concerning these glands follow.

Endocrine means internal secretion. The glands which chiefly furnish this secretion are the pituitary, pineal, thyroids and adrenals. These are the main links in the socalled endocrine chain. Others which play a part are the thymus, pancreas, spleen and gonads.

The pituitary (third, or small brain), has an anterior, middle and posterior part. By some observers (chiefly Sajous) it is said to dominate the chromaffin system. Cysts and new growths are its frequent diseases. This gland's secretion has much to do with body growth. Overgrowth, giantism, and acromegaly, are due to overactivity of the gland; the first two take place before, the third after, ossification of the epiphyses. The pineal gland has some influence on growth but is not so well understood.

THYROIDS

Goitre is popularly classified as follows:

1. Colloid:—This enlargement of the gland is seen in early adolescence, most frequently in the female, has a soft velvety feel, is symmetrically enlarged, and should never be operated upon. Iodine is helpful in its management.

2. Adenomatous:—Two types exist, a, the simple adenomatous, and b, the toxic adenomatous. With this form of goitre there is little or no exophthalmos and no body tremor, or loss of weight, and the basal metabolic rate is not greatly altered. Usually the right lobe is enlarged. Parts of the gland may contain single or multiple adenomas and often escape detection. The toxic type seriously damages the heart. The treatment is medical for type a, and surgical and medical for type b.

3. Exophthalmic (Graves's, Basedow's or Perry's disease): This type is diagnosed by exophthalmos, tremor, and tachycardia. The gland may not be perceptible, but usually is enlarged. It may be substernal, even retrotracheal. Loss of weight, insomnia, gastric crises, diarrhea, and psychoses may result from this disease. Exophthalmic goitre is not due simply to excess of thyroid secretion. The surgeon may remove enough of the gland to cause myxedema and the patient still show symptoms of exophthalmic goitre. The basal metabolic rate is increased. Treatment is surgical and medical.

Other diseases, such as neoplasm, both malignant and benign, acute inflammation, abscess and cyst, are a few of the many which may attack the thyroids. Aberrant thyroid is a possibility.

Cretinism is of several types, early and late. It results from too little thyroxin, the thyroid's active principle. It may be due to congenital absence of the gland, or disease causing it to atrophy. The treatment is the administration of thyroid extract very early and a sufficient quantity given over a long period.

Myxedema is the same thing only it takes place later in life. Examples may be seen following some operations upon the thyroid for goitre. It does not happen now so frequently as formerly, because few surgeons do total thyroidectomies.

Tetany has developed following the accidental removal of the parathyroids. It is recognized by intermittent tonic muscular spasms of the hands and arms and increased excitability of the peripheral nerves. The treatment is calcium lactate, U. S. P.

Focal infection plays an important rôle in causing disturbances of the endocrine glands. It should always be diligently sought for and when found removed, if possible. Habits of thought and living (faulty in nature) should be studied and rectified.

ADRENALS

These furnish the body with a substance called adrenalin. Addison's disease is one in which there is hypoadrenalism—a disease which is evidenced by a peculiar bronzing of the skin, loss of strength, low blood pressure, diarrhea, and slight anemia. It is fatal. The cause is destruction of the adrenal tissue. Tubercle bacillus can do this, also cystic degeneration, neoplasm and injury. There are mild grades of hypoadrenalism, for example—seen during convalescence following acute fevers, during long continued toxemias, and mental and physical overwork.

GONADS

The terms hypogonadism and hypergonadism refer to ovarian and testicular internal secretory functions. Some dispute that these chromaffin organs have an internal secretion. That they have a big rôle to play in metabolism is clearly demonstrated by the castrated animal (the eunuch or agonad). The ovariectomized or testiculized female or male takes on the opposite sex characteristics. Especially is this true if castration is done before the formative and sex functioning period of life is over. If afterwards, these changes are not so marked.

Recently there came to my service an exsoldier who, when a child, lost one testicle from injury. The other compensated until a gunshot wound during the late war caused the loss of the remaining gland. Soon his voice became high pitched, his hair thin and soft, and fat deposits of breast and hips gave him the appearance of a female. He was twenty-four when he suffered his last accident. Ram's testicular tissue injected subcutaneously once every ten days or two weeks, caused a loss of thirty-five pounds, his voice and features became more masculine and he expressed himself, "I feel much improved." Such treatment is not lasting in effect.

Today surgeons are conservative when doing pelvic surgery. They leave functioning parts, if not all of the ovaries, for the reason that an ovariectomized woman takes on masculine changes. This is notice-

*The last of six clinics for Senior Students of College of Medical Evangelists, held April 29, 1926, at the Los Angeles General Hospital.

able in some women during the menopause, due to atrophy of these organs Often they improve when given sheep's ovary and thyroid gland extracts.

A definite relationship exists between the thyroids and ovaries. Three times in a woman's life is her thyroid liable to change—at puberty, during gestation, and in the climacteric period. Frequently during menstruation the breasts and thyroids are more full and sensitive.

Uterine disease, for example, fibroidosis, fibroid and other tumors, frequently are associated with thyroid dysfunction. The converse is also true. With thyroid disease, uterine disturbances such as amenorrhea, and dysmenorrhea, are often the chief complaints which bring the patient to the physician.

The endocrine glands are interrelated. Thyroid disease may involve the thymus. Many problems, e. g., status lymphaticus, menopause, puberty, obesity, pathological sleepiness, high blood pressure, low blood pressure and many other conditions still remain unsolved. Do not forget that the pancreas is one of the organs of internal secretion.

Illustrative Case by Intern Dr. G. W. Harmon: No. 246521, a Mexican, male, single, aged thirty-two, complained of "nervousness for three years, worse the last two months; weakness, and irritability." He had lost forty pounds during the last two years; had difficulty in swallowing, diarrhea and borborgymus; all coming "in attacks." He had been worse the last two months since the death of his father. (Dr. Shuman—"Note the effect grief has in the production of attacks of thyroid toxicity."

Physical examination.—Undernourished and over alert; exophthalmos without marked Von Graefe's, Stellwag's and Moebius's signs; tonsils diseased; a bilateral enlargement of the thyroid, which was firm and elastic; a systolic murmur heard over the gland; there was expansile pulsation of the gland; tachycardia (105); blood pressure 135-75; a fine tremor of the outstretched fingers; cutaneous bronzing and reflexes lively.

Laboratory findings:—Blood, white blood cells 4,650; lymphocytes 47 per cent.; urine, specific gravity 1.018 and a trace of albumin. Basal metabolic rate, plus 48 per cent.

Diagnosis, exophthalmic goitre; treatment, medical, later surgical.

2007 Wilshire Boulevard.

Studies with Thyrotoxic Blood and Adrenalin

Presence of a Toxic Element

ROBERT L. PITFIELD, M.D.
Germantown, Philadelphia

In a previous paper (1) I described some experiments in which the injection of one cubic centimetre of serum from a thyrotoxic case into a white rabbit followed by instillations of one to one thousand solution of adrenalin induced mydriasis. In the five cases of toxic thyroid all reacted while in the controls reported in that paper there was no reaction. I have found that it is essential to use white (female) rabbits in the experiments and pregnant females seem to be more sensitive than others. In one experiment five mgs. of thyrotoxin injected into a rabbit with instillations of adrenalin beginning immediately afterwards no mydriasis was induced, the animal died within twenty-four hours. Not only was there no mydriasis, but the eyes became sunken, the animal was distressed, panted heavily and rapidly and succumbed to the poisonous effects of the thyrotoxin in this huge dose.

A portion of a very toxic adenomata, recently removed from a woman, whose history is detailed under S. B. later in this paper, was washed clear of blood then finely macerated and the juice of the tissue squeezed out in sterile gauze. Two c. c. of this fluid was injected into a rabbit and adrenalin instilled intensively every four minutes. Total mydriasis was produced in forty minutes by the instillation of twenty drops of adrenalin solution.

One c. c. of this thyroid tissue extract was mixed with .25 c. c. of adrenalin and injected into another rabbit, after the lapse of eighty minutes there was no sign of mydriasis.

As controls other sera from sick persons was employed, one c. c. of serum from a young man with acute syphilis produced mydriasis with the addition of adrenalin instilled into the rabbit's eye, the same amount of serum from a woman suffering from the toxemia of pregnancy produced a mydriatic reaction in the same way under like conditions.

Feeling that other toxic matters might cause the reaction, one half c. c. of typhoid vaccine containing over five hundred million of bacilli was injected into a rabbit and the adrenalin technic followed, no reaction appeared in eighty minutes.

A Jewish woman, aged thirty-six, married and mother of three children, long a sufferer from diabetes with a blood sugar under fasting of 176 mg.—to 220 mg. was tested for this mydriatic reaction. It was felt that since adrenalin, according to Loewi, if dropped in the eye of a diabetic will produce mydriasis. Two c. c. of this woman's serum was injected into a rabbit (that had previously reacted to toxic thyroid sera) at 5.08 p. m.

Adrenalin was instilled according to the technic previously described, two drops every four minutes. At 5.54 after twenty-four drops had been instilled and forty-four minutes had elapsed a mild and transient mydriasis appeared. At 6.10 p. m. after one c. c. of adrenalin had been instilled and an hour had elapsed, no fixed mydriasis had appeared, the pupil responding to light intensively applied to the eye.

This experiment was repeated on the same rabbit, when the blood sugar had increased from 176 to 240 mgs. A transient and incomplete mydriasis was produced, the pupil responding to light sluggishly.

This case illustrated the value of the reaction to a clinician. A woman with an enlarged thyroid,

mental symptoms, rapid pulse, weak heart and presenting other symptoms strongly suggesting hyperthyroidism was tested, one c. c. of her serum failed with the aid of adrenalin instillations to produce a reaction after the use of one c. c. of adrenalin and the lapse of ninety minutes. Her doctor told me afterwards that her metabolism was found to be minus eighteen and that she improved greatly under thyroid feeding.

In my previous paper I described one experiment in which the blood from a highly toxic case persisted in causing a reaction after it had been heated to 58° C. for 140 minutes, one half c. c. was sufficient to produce the reaction. The hypothetical substance was not destroyed by heat, and is thermostabile. In the next case I hope to show that the influence of light and oxygen are deleterious. It will be noted that serum that was active soon after withdrawing the blood, lost its mydriatic powers after standing in a room exposed to bright light for seventy-two hours. It will be also noted that serum that reacted in white rabbits failed to do so in young New Zealand animals.

CASE I.—Mrs. E. K. seen with Dr. Swartly. Chief complaint nervousness, palpitation of heart, apprehensiveness. Examination, emaciated female sixty-four years of age, pulse rapid 108, had been up to 120 many times. Thyroid enlarged, hard, adenomatous. Blood pressure 180 systolic. Had been subject to diarrhea which had been hard to control. Had a fine tremor, moist skin, was weak and dyspneic on exertion. Had mild hemiplegic attack recently. Had proptosis of eyes, forehead did not wrinkle, on looking up. Had no Dalrymple, Stellwag or Von Graefe signs. This was without doubt a case of toxic thyroid disease.

At 5.26 one c. c. of her serum was injected into healthy white female rabbit (No. 6) had been used before in these experiments.

After a lapse of thirty minutes and the instillation every four minutes of two drops totalling eighteen drops of adrenalin one to one thousand solution (.54 c. c.) complete mydriasis occurred. The mydriasis began to appear at the end of seventeen minutes but was not complete until thirty minutes had elapsed.

Mydriasis persisted until the end of 180 minutes, eye was proptosed during the experiment, pupil in other eye was not mydriatic, but at the end of the experiment it was somewhat sluggish but not in the least dilated, responding to the stimulus of light.

One c. c. of this same serum, Mrs. E., was injected into a brown male New Zealand rabbit at 9.26 p. m., at 9.29 two drops of adrenalin one to one thousand was instilled into its left eye, this was repeated every four minutes until 10.59, the lapse of ninety-five minutes, forty-six drops of adrenalin was instilled. The usual early and false mydriasis noted in these experiments (due to adrenalin alone) appeared, this quickly vanished and the pupil was mobile until the end of the experiment contracting fully to the stimulus of the light. The absence of the reaction I believe to be due partly to the breed of the animal and partly to the sex. The other experiments were done on white female rabbits almost exclusively.

Protocols of experiments on Mrs. E. K.'s serum, a highly toxic case of goitre are presented herewith.

This woman died in two months after this examination of thyroid disease.

EXPERIMENT No. 1—WHITE FEMALE RABBIT

1 c.c. serum injected at 5.26 p. m.
2 gtt adrenalin installed at
5.27
5.31
5.35

3.26 pupil markedly dilated but reacted to light
3.30
After the lapse of forty-two minutes mydriasis appeared but it was not fixed; twenty-four drops of adrenalin used at the end of ninety minutes pupil was dilated still but reacted to light.

EXPERIMENT No. 4—WHITE FEMALE RABBIT

1 c.c. Mrs. Eukers serum was seventy-two hours old, kept at 60°F, exposed to light; serum injected at 2.12.
2 drops adrenaline instilled at
2.14
2.18
2.22
2.26
2.30
2.34
2.38
2.42
2.46 pupil dilated but reacts to light actively
2.50
2.54
2.58
3.02
3.06
3.10
3.16 pupil continues to react to light but dilated
3.30 pupil dilated but contracts. Reaction negative, the same rabbit used, also the same eye. The reaction did not occur because of staleness of serum, which was seventy-six hours old.

CASE II.—R. C., male, aged forty. Adenomatous goitre bilateral. Patient admitted to the wards of hospital suffering from rapid pulse and loss of weight. He complained of marked weakness of arms and legs and of difficulty in swallowing.

He was easily excited, the sight of a running dog almost set him wild. His heart ran wild upon excitement and exertion. He perspired easily and became weak. He experienced dark flashes before his eyes. His hands became moist and clammy under slight excitement. He had lost thirty-seven pounds in eight weeks. He suffered from diarrhea when he was ill with an infected knee.

Physical examination revealed a markedly emaciated weak man. A slight cough could easily be explained by pressure on the trachea by a huge bilateral adenomatous goitre. This was hard and seemed to be composed of three distinct lobes. His heart was rapid, a systolic murmur was noted. Apex beat was just outside the nipple line. Sounds weak, pulse Corrigan in type. Trauba's pistol shot phenomena was noted in the femoral artery.

Blood pressure 120-65. The lungs were clear. His nervous symptoms were chiefly mental. Except for a fine tremor of the extremities and exaggerated reflexes of the leg, no other signs were noted. No eye signs were present, excepting that his pupil dilated if his neck on the same side was pinched.

His teeth were in a septic condition, and an abscess of the leg four months previous to his entrance to the hospital probably fired the loaded gun, enlarging his thyroid and rendering it toxic. Metabolism on ad-

mission was 109 plus, this fell under rest and iodine to 39 and 32.

The Goetsch test was applied, his pulse rose from 90 to 120 and his blood pressure also rose from 120 to 140 in thirty minutes. The pulse continued to be fast for about one hour after the test, during which he was most uncomfortable. He declared that after receiving the adrenalin he felt as if he were a clock from which the pendulum had been removed so rapid was his pulse that it resembled the rapid ticking of a time piece. When the pulse rate subsided to its former condition he said that the pendulum is on again.

One c. c. of the patient's serum was injected into a white male rabbit, and adrenalin applied for over an hour to the left eye, no mydriasis appeared. It is possible that the serum was not absorbed. Another rabbit was used. One c. c. of serum was injected into it and adrenalin instilled after the lapse of thirty-three minutes and the use of eighteen drops of adrenalin total mydriasis appeared. The reaction was strongly positive.

After the metabolic rate had declined to its lowest point and then when it began to ascend again a polar and superior thyroid artery ligation was performed on the right side under gas anesthesia. The patient stood the operation extremely well, reacting rather markedly for a few days. The right thyroid enlargement then became softer and smaller.

Subsequently this man after a long rest was operated upon and a subtotal removal of the gland was accomplished by Dr. Charles Mitchell. From this he recovered. Fifteen c. c. of blood were mixed with an equal amount of sterile water and this was distilled slowly in a retort. The first two c. c. of the distillate was injected into a rabbit and adrenalin solution instilled as in the other experiments. After forty minutes and the use of twenty gtt. of adrenalin solution total mydriasis appeared. This is of interest in that it apparently shows that the hypothetical substance is not only thermostabile but is of a volatile nature.

Case III.—Mrs. Stella B., a Polish woman, married, mother of three children, presented every sign of toxic thyroid except eye sign. Her heart was rapid and weak. She exhibited a marked tremor of hands and tongue. Her mental condition and facial expression were such as to suggest a psychopathic condition. She was emaciated, extremely pigmented, and so nervous that sedatives had to be constantly administered to her. The thyroid exhibited marked enlargement in both lobes and isthmus. It was of the adenomatous type. Her teeth and tonsils were septic. Her physical examination otherwise was unimportant. Her metabolism was plus 50.8 after remaining in the hospital it rose to plus 90, a subtotal operation was rapidly performed by Dr. Charles Mitchell. From this she recovered, suffering several attacks of pulmonary edema subsequent to the operation. These attacks were relieved by the administration of atropine and digitalis.

Serum from this woman was injected into a white female rabbit and the adrenalin technic followed as in the other experiments, after the lapse of fifty minutes and the uses of twenty-six drops of adrenalin, a total mydriasis appeared, this persisted for four hours.

In another experiment the serum from this woman was heated in a water bath for ninety minutes at a temperature of 55° C. then the heat was raised to 65° C. for ten minutes. This on injection into a rabbit and adrenalin instilled in one eye mydriasis appeared as before and the reaction was certainly as positive with the heated as with the raw serum.

Eighteen days after this woman had been operated on, she was again bled and her serum injected into the same rabbit to which it had reacted previously. After the lapse of forty minutes there was a sluggish mydriasis which was not total as this reaction demands. After the lapse of an hour and the use of over one c. c. of adrenalin solution there was no mydriasis, both pupils reacted in the same manner to light intensively applied to the eye. If any inference can be drawn from this one experiment it would seem that the thyroidectomy removed the toxic principle from the blood stream. The gland itself produced a reaction after washing and maceration in salt solution as described.

Case IV.—Mrs. B—y, a married woman aged forty-one, was admitted to hospital complaining of heart weakness, high blood pressure and weakness. She had had the usual diseases of childhood, menses regular until last year when they became irregular. One child died at birth. For eleven years this woman had suffered from a toxic thyroid. About this time Dr. Charles Frazier performed a bipolar ligation with temporarily good results. Then she suffered from tremor, heart palpitations and the gland was noticeably enlarged. Physical examination revealed a firm large thyroid gland easy to palpate. So firm was it that an adenomatous change was suspected. Her hand trembled on extending the fingers. There were no eye symptoms. Her heart was not enlarged, a mitral murmur systolic in time was easily detected, there was no decompensation, no edema of the extremities. Her basal metabolic rate was 81.7 pulse rate over 120, and blood pressure 230, no diastolic. The woman was apprehensive and nervous. Being of a very low order of intelligence it was difficult to examine her mental condition. Evidently she was anxious and in mental distress. One c. c. of her serum was injected into a healthy young male New Zealand rabbit. After the lapse of two minutes two drops of adrenalin one to one thousand was instilled into its left eye, this was repeated every four minutes until one c. c. of this reagent had been instilled, after the lapse of seventy minutes there was no reaction.

Thinking that perhaps the sex of the animal and the race might have had something to do with the non-reaction, the experiment was repeated, a white (albino) female rabbit was used as in some of the other experiments.

One c. c. of serum was injected into it and adrenalin intensively instilled every four minutes into its right eye. After the lapse of eighteen minutes and the use of ten drops of adrenalin the pupil became sluggish. After fourteen drops of adrenalin and the lapse of twenty-four minutes full paralytic mydriasis appeared. The pupil was immobile to the stimulus of a bright light held close to the cornea for half a minute. The inference from this experiment being that the New Zealand rabbit was insusceptible to the toxic effects of the reagents. The woman died a month after this.

Case V.—Mrs. A. K., aged twenty, married, mother of one child. This case is a borderline of either neurasthenia or nervously unstable, or toxic goitre, incipient. She was nervous, had a tremor, anxious over trifles. She had had some of childhood diseases, but was never extremely sick with them. Had had sore throat frequently as a child. Had been very sick with influenza.

Physical examination, thyroid easily seen, palpable. Eyes prominent and bright. No Stellwag or Von Graefe sign, hands showed marked tremor. Hand became moist on excitement, no diarrhea. Pulse rapid, rate 100. Had no cardiac abnormalities of rhythm except a juvenile sinus arrhythmia. Menses regular five days, painless. Tonsils septic in appearance. Subsequently these were removed.

One c. c. serum injected into white female rabbit at 6.47 p. m. It was hard to determine the exact time of the mydriasis it came on early but was not complete until about fifty minutes after the serum was administered.

Protocol

6.48 two drops adrenalin 1.1000 instilled in right eye and repeated at every time notation.

7.26 " " " " " " " "
7.30 " " " " " " " "
7.34 " " " " " " " "
7.38 Complete mydriasis at this time, pupil widely dilated does not respond at all.

Reaction positive, fifty-one minutes 26 drops or (.78 c. c.) adrenalin one to one thousand administered. Probably less adrenalin needed. According to the findings of this reaction the case is one of incipient thyroidism (toxic goitre).

Five months after the reaction was obtained, patient was again examined clinically in the lower portion of the left lobe of the thyroid a small adenoma was detected, this was moderately firm, patient's condition about the same. No metabolic estimation was done.

Case VI.—Mrs. C. C., a married woman aged forty-one, in the wards of the Chestnut Hill Hospital. Her chief complaints were weakness, palpitation of the heart, nervousness and mental unrest. She suffered from some neurasthenic pains in the chest. She had had an acute nephritis, three years previous to coming under observation, with edema of the feet. She also gave a history of dyspnea for years. In her childhood she had had scarlet fever, followed by an abscess of the throat and blood infection. In 1925 she had pneumonia. One month before her admission to the ward she said a goitre developed in her throat. She had frequent attacks of appendicitis. Her dyspnea and nervous debility prevented her from working about her home. She was the mother of eight children.

Physical examination revealed a blood pressure of 140 systolic, a metabolic rate of 37.8, a blood sugar content of her blood of 111 mg.—100 c. c., nonprotein nitrogen 11.2 mg.—100 c. c., sulphophenolphthalein excretion 72 per cent. in two hours. Her heart was not enlarged, pulse rapid over 120 frequently. The thyroid was slightly enlarged. Her heart while rapid and weak was without any abnormal signs except those noted. There were no eye symptoms.

This woman had had many toxic infections paving the way for thyroid disease. Nevertheless it appeared to be a borderline case of either neurasthenia or toxic thyroid. One c. c. of her serum was injected into a white rabbit, female. Adrenalin one to one thousand solution was intensively instilled every four minutes into the left eye. After the use of thirty-three drops of serum at the expiration of seventy-four minutes, mydriasis was complete in the eye. There was no proptosis of the bulb after this intensive use of adrenalin. The case was possibly one of mild thyroid intoxication.

Case VII.—Sarah E., aged nineteen years. Toxic goitre, when twelve years of age, one lobe of her thyroid had been removed previously. Her mother had had toxic goitre and died after an operation for it. Father was well and hearty. She had had the usual diseases of childhood excepting diphtheria.

Her heart was normal, pulse slow 72-76, weight 170, metabolic rate 31 plus. Her skin was glossy and satiny. The thyroid lobe was enlarged. An old scar of a previous operation was manifest. There were no nervous symptoms excepting a slight tremor. No eye symptoms were present. Her forehead did not wrinkle, but her pupil dilated when skin of neck was pinched on the same side. There were no mental symptoms. She seemed stolid and placid. Was unable to work as a nurse because of her weakness. Had been taking iodine (Lugol's solution) for three weeks previous to examination. One c. c. of her serum was injected under skin of white male rabbit half grown at 5.05 p. m. Two drops one to one thousand solution adrenalin instilled into left eye at the following intervals:

5.06
5.10
5.14

6.10
6.14 Thirty-three drops of adrenaline used no mydriasis, reaction negative.

Reaction negative, pulse also slow, high metabolic rate indicates goitre of toxic nature but there was no mydriasis, perhaps the treatment had something to do with this. It appears from this case that the absence of a mydriatic reaction is consistent with the normal pulse. The reaction was useful to me in the following case.

Case VIII.—This patient had been treated by various physicians (including myself) for an apparent neurasthenic condition. She had a rapid pulse, faint feelings about the precordia, and a fine tremor of her fingers when excited. She also exhibited an anxiety neurosis. There was not the slightest indication from the woman's appearance that she suffered from hyperthyroidism. She was thirty-eight years of age, strong, vigorous looking; there were no eye symptoms, in the neck there was no sign of thyroidal enlargement, nor could the gland be palpated. She exhibited a pair of septic tonsils, otherwise her physical examination revealed nothing except some substernal dulness extending each side of the manubrium; this area was three and a half inches in width by one and three quarters in height. Her weight was 165 pounds, height five feet eight inches. Her blood pressure 170 systolic, her pulse was rapid. She said that for nine

years it had been so, being worse at the menstrual times. The abdomen was negative, so was her pelvis. Trying out this reaction on her, in view of the substernal dulness and absence of thyroid in neck, a prompt reaction occurred after the lapse of twenty-eight minutes and the use of fourteen drops of adrenalin. Then an x ray was made, a mass was revealed high in the apex of the thorax, also some calcareous glands in the hilii of both lungs. A basal metabolism test was done and a finding of plus 40 found. Subsequently her septic tonsils were removed and now she is having radium treatments to the substernal thyroid, which evidently, from the reaction of the serum and adrenalin in a rabbit, from the high metabolic rate, rapid pulse and tremor, must be of a toxic nature. Without the use of x rays and other modern measures a diagnosis could not possibly have been made. The positive reaction made me suspect the nature of the complaint.

In a previous paper I said that I believed that the administration of iodine by a suspect before trying out the reaction interfered with it. From subsequent experience I am led to the belief that this agent has no direct or immediate effect.

This method, if it proves to be reliable, should have an appeal to those practitioners who have not access to a metabolism apparatus. A few rabbits, two syringes, a test tube, an eye dropper and some adrenalin solution being all that is required save a time piece.

I wish to thank Dr. Roy Langdon and my excellent intern, Dr. Ira Towson, for aid in persuing these studies.

CONCLUSIONS

It has been the object of this paper to endeavor to show that there is constantly in the blood stream and sometimes in the thyroid gland itself (not thyroxin) a chemical poisonous entity which has certain physical properties. It can resist heat even to 100° F., can be distilled and retain its mydriatic properties. It is destroyed by exposure to light and oxygen after forty-eight hours. It seems to be of value in the diagnosis of toxic thyroid disease and the relative severity of the disease can in a measure be determined by the time of the appearance of the reaction and by the time that it persists. It is dependent upon the nervous susceptibilities of an animal with illy developed autonomic system. This is a very crucial factor to take into consideration.

SUMMARY OF ALL CASES

I. Cases in which there was no reaction (nontoxic thyroid disease).	
Diabetes	1
Hypothyroidism	1
Normal controls	2
Symptomless thyroid enlargements	2
	6
II. Cases in which there was a reaction and in which there was no suggestion of thyroid disease:	
Syphilis acute	1
Toxemia of pregnancy	1
	2
III. Thyroid enlargements with toxic symptoms no reaction (cured?)	1
Thyroid enlargements with toxic symptoms positive reaction	12

The Endocrine Glands of Rats in Parabiosis*

PROF. GIACOMO PIGHINI, M.D.
and MARIO DE PAOLI, M.D.
St. Maurizio, Italy

Under the term parabiosis Sauerbruch and Heyde are understood to designate that state of altered individualism which arises when two animals are united in such a way that their organic circulating fluids become susceptible of mutual interchanges. More than a parallel life in the two animals so united, such as the word parabiosis (para) indicates, a material and energetic exchange takes place between the two organisms without altering their separate individuality; whence this new condition may be better designated by the phrase symbiotic grafting coined by Schoxel, or the rats and rabbits joined in this manner may be more simply called Siamese animals, as Morpurgo does.

What interests us is the fact that, when two animals of the same species are united together side by side in such a way that their circulating fluids mingle over all the bleeding surface and are diffused interchangeably in the two organisms, experimental physiopathology affords us in this way a means of attacking a number of problems involved. No need to mention the numerous applications made of this method in these last fifteen years since Sauerbruch and Morpurgo in 1908 published their first interesting observations on the subject. The aim we have set in undertaking the present study is that of ascertaining if in this way some light may be thrown on the obscure problem of the humoral correlation between the different endocrine glands, and as a branch of this to approach the problems of sexuality, of sexual individuality, of the relation between the sex glands and the other organs and secretions of the body. The few studies hitherto made in this direction afford an excellent hope of obtaining some good fruit.

It was a Japanese investigator, Matsuyama, who first drew attention three years ago to the secretory and glandular reciprocity mutually existing between two animals of the same species united in parabiosis when one, for example, is castrated and the other not, or when of different sex. He employed white rats in his experiments and obtained, briefly, these results:

The first marked alterations noted in parabiosis of a male with a female were in the sex glands of the

*From the Lazzaro Spallanzani Scientific Laboratory of the Reggio Emilia Psychiatric Institute, directed by Prof. G. Pighini.

Siamese pair. Only in the early period did corpora lutea develop in the ovaries; at a later period, instead of this there was increase of the interstitial gland and formation of numerous cysts. The testicles developed abundantly in the early stage only, and degenerated in succeeding stages. The changes in other organs appeared in the second stage and were consequent on those of the sex glands. When these were markedly degenerated, the uterus presented degeneration and atrophy and the adrenal capsules and the thyroid showed the same type of alteration as is encountered after castration; thus only the anterior lobe of the hypophysis was changed, as after castration or during pregnancy.

If a male is admitted to such a couple, the female of the pair does not conceive; in like manner, the male of the pair is incapable of impregnating females. But on supplying a male to a pair of females joined in parabiosis, both of these may beome pregnant. On the other hand, the endeavor has always been unsuccessful to impregnate a female united to a castrated male or with another female which has been castrated: this results from the alterations brought about in the ovary or uterus of the uncastrated female. The alterations in other organs in the latter instance are proportional to those which have taken place in the castrated companion. Thus, in the advanced stage there occur atrophy of the uterus and mammæ, hypertrophy and increase of lipoids in the adrenal cortex, hypertrophy of the medulla, increase of large basophile cells, the socalled cells of castration or pregnancy, in the anterior pituitary lobe, with deficiency of cyanophile cells.

From this and other observations Matsuyama concluded that the hormones arising from the testicles and ovary act in a way antagonistic to one another, and cause modifications in the adrenal capsules, the pituitary and mammary glands, which become apparent in castration, in pregnancy, and in parabiosis between male and female through the degeneration or atrophy undergone by the ovarian follicles. Even pregnancy and the suppressed genital function of the masculofeminine pair in parabiosis must be considered as a state akin to castration.

FIG. 1.—The seventh pair of rats, the female dying on the seventeenth after operation.

This theory of the Japanese investigator has been thought extravagant and has received much criticism in certain very recent studies of the subject. Mayeda, for example, in rats of different sex in parabiosis did not find histological alterations of the sex glands, and especially of the testicle. Schmidt, one of Sauerbruch's pupils, calls in question the failure of the female in such a pair to conceive. Nissen and Romies deny that the resultant alterations depend on antagonism between the hormones of the two opposed sex glands, but consider that they proceed rather from dysharmonic parabiosis, from reciprocal intoxication due to the different metabolisms of the two organisms artificially united.

In view of these contradictory interpretations and observations it has seemed of interest to follow out from their origin the experimental studies in this field of research as concerns glandular correlations. We, too, have chosen white rats, formerly recognized by Morpurgo as best suited to studies of this sort, and began our experiments by uniting together males with nongravid females, always selecting animals already sexually mature, from five to eight months old. The experiments were made by the two most common methods of parabiosis—union side to side of the thigh muscles and of the skin over a considerable width forward to the region of the axilla and the neck—or union of the two peritoneal cavities internally and the skin externally. The latter procedure, however, most frequently resulted in death within twenty-four hours and was abandoned in favor of the former. That a direct exchange of fluid took place with simple musculocutaneous junction was proved in all our rats in parabiosis by finding iodine in the urine of one individual when a solution of iodine had been injected into the other member of the pair. The result of this test was always positive.

Twenty pairs were studied in all; but we present the anatomicopathological reports of only twelve of these, selected among the more significant. We excluded from study ten other pairs which resulted badly through poor union and the production of fetor at the juncture, or through septic cavities in the animals. The principal facts are reported respecting the twelve pairs of animals examined, in the order of increasing duration of parabiosis. Only one of these is a parabiosis of male with male. Of two other pairs of males the data are omitted, so as not to encumber the table. All the others are between a male and a female.

In this series of experiments pairs of young animals received the preference, those of the same age and weight when possible, the youngest two months, the oldest eight, the greater part from three to five months, or at the epoch of initiation of sex function. Each couple was kept in a separate cage and fed a varied diet of wheat, maize, rice, bread, raw vegetables, and a few bits of cheese.

The twelve cases described below, all chosen among the most noteworthy, offer results for the most part confirmatory of one another, so that a characteristic type of somatic and histopathological reaction is possible to determine from this experimental condition (Fig. 1).

The first two pairs were killed the day following the operation; of the third, the male died after four days and the female was sacrificed (with chloroform); of the fourth, the female died after eleven days; both of the fifth pair died on the twelfth day; both of the sixth pair on the fifteenth day; of the seventh, the female died on the seventeenth day; the eighth was killed the twentieth day; of the members of the ninth couple, one died on the twenty-second day and then the other also was killed; the members of the tenth pair were killed on the thirty-first day; those of the eleventh died on the sixty-fourth day;

those of the twelfth were still in full health on the 165th day and were then sacrificed. Death was inflicted either with chloroform or by drowning.

As may be seen, a considerable part of our rats were killed suddenly in the first seven days following the operation of parabiosis, and the reason was that they all had become toxic. But there were pairs which had resisted long, and others which would certainly have resisted to the end, if they had not been sacrificed. Thus, omitting the cases of death from probable infection, there remain four cases in which it may be maintained that the cause of death was grafted in that condition of mingling of fluids into which the animals were brought by the cross bleeding of the operative procedure.

The disturbances produced by this condition become manifest immediately after the operation. Not longer than fifteen to thirty minutes later the animals become restless, agitated, at times furious and bite one another, until they reach a state of trembling after a few minutes of severe shaking, which may become a tonic clonic jerking and amount to a true convulsive seizure. This state lasts some time, until the animals recover and begin first to drink and then to eat. Frequently congestion of the conjunctiva is noted, even capillary hemorrhages into the sclerotic. Another phenomenon constantly observed the day after the operation is considerable edema of the testicles, but this probably results from extension of the irritative process in the superficial tissue adjoining the incision.

These phenomena were encountered by us in every pair of Siamese animals, whether of male united to female or of male to male, whether in those operated on by celostomy or by musculocutaneous suture (decidedly accentuated in the latter), and afford, in our view, proof of an evident reaction of the nervous system to the mutual intoxication which the secretory exchange in one member of the pair exercises on the other, an acute intoxication which is later modified by mutual immunization.

This immunization is not so sufficient and complete as to preserve the two associates from the ultimate harmful effects of their histohumoral marriage. We have seen that the majority of couples tend, after a varying interval of time, to emaciation and death of one of the members, carrying with this the death of the other (generally we at once forestalled the final death of the surviving companion).

On autopsying the dead companion signs were not found of special affections in any of the individual internal viscera, to which sickness and death could be ascribed; these were all greatly congested in comparison with those of the comrade, a fact already noted by Matsuyama and others and due probably to relaxation of vascular tone in the one first dead. But the changes observed in them on histological examination differed very little from those seen in pairs killed in a condition of unquestioned health. These changes, as we shall see, are characteristic of such pairs and betray the toxic condition to which the entire organism is subjected, a condition not severe in some pairs and well borne by them, in others illy tolerated, especially by one or other of the partners. Usually it is preceded by hypotrophic phenomena, in one leg for instance, in the tail, which may become gangrenous, and by falling out of the hair.

The reasons for variability in individual reaction are difficult to determine. They reside in the special constitution of each individual, which causes the humoral combination of the two to result in individuals of similar or of quite different constitution and histochemical interchange.

We were careful to select always for every union animals of the same age and the same stock, bred for years in the same way in our establishment. In spite of this, the variability of the reactions was very marked. Only in pairs born in the same litter and operated on at the youngest age (as in the seventh pair, operated on at fifty days old) did mild reactions occur and a greatly prolonged duration of life.

ANATOMICOPATHOLOGICAL EXAMINATION

The principal anatomicopathological facts are given in the table. Above all it is worthy of remark that all the animals at time of death, as well spontaneous as artificially produced, had lost weight, and especially those whose body development was completely attained. Exception is made of the seventh pair, whose members weighed respectively sixty grams and fifty-five grams at the age of fifty days and 180 grams and 140 grams when they were sacrificed after 165 days. The other pairs united in the same way manifested at the same age and throughout the experiment a regular progress of depletion.

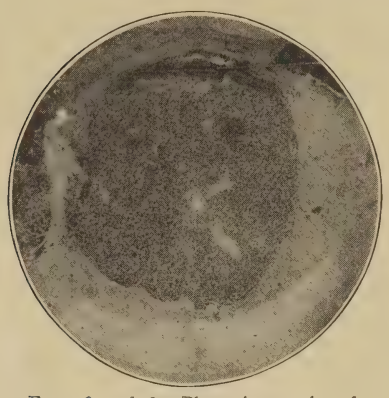
Macroscopically the different viscera had a different appearance according as the animal died before its companion or both were experimentally killed. In animals dying first in a pair, as already said, all the viscera, and especially the pituitary gland, the liver, and the spleen appeared turgid with blood. In many of the males sacrificed in apparent health a volume, a weight, a consistency of testicles were noted which were below normal.

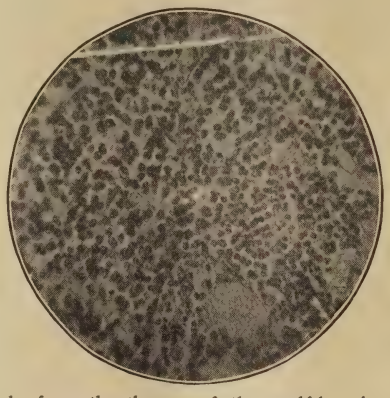
Parts of the different viscera were fixed suitably for histological examination. The fluids used by preference were formol and a mixture in equal parts of ten per cent. formol with saturated solution of bichromate of potassium for the brain, pituitary, lungs, liver, kidneys, adrenal capsules, pancreas, testicles, and ovaries. The thymus was fixed in absolute alcohol, the sex glands in Carnoy's solution, Tellyesniezki's, Sanfelice's (one per cent. chromic acid 160 c. c., formalin eighty c. c., acetic acid ten c. c.), Flemming's, Ciaccio's, with appropriate staining (for Carnoy staining with Pappenheim and Biondi, for Tellyesniezki and Sanfelice with Regaud's blood alum and safranine, for Ciaccio with Sudan III and hematin). These necessary matters of technic being understood, it becomes possible to follow in the ovaries and especially in the testicles all the phases of the germinal cells, and in the latter the various nuclear forms (chromosomes, etc.) of the seminal sequence. (Excellent preparations were obtained from the testicles with Sanfelice and Tellyesniezki.) In order to estimate the lipoid and anisotrope substances (by the polarizing microscope) the adrenals, ovaries, and testicles were sectioned after fixing in formol and bichromate of potassium and hardening and then were stained with sulphate of Nile blue.

The essential facts will be enumerated which were observed in individual organs by histological examination, and inferences will then be drawn, by considering them in comparison with the normal organs of

rats of the same age, as to the effects of the condition of parabiosis in animals.

One of the first organs to undergo modification in the state of parabiosis is the thymus. It was constantly found altered in pairs which did not survive beyond twenty-four hours after operation, and always more changed the longer they had remained in this susceptibility to staining together with its outline (with hematoxylin and Pappenheim it becomes always a clear violet, while the cells still remaining integral of the neighboring area maintain their deep blue coloring). The cell membranes assume the appearance of shapeless masses, which evidently end by disintegrating and being absorbed. When these





Figs. 2 and 3.—Photomicrographs of a lobule from the thymus of the twelfth pair. Cp. plasma cells.

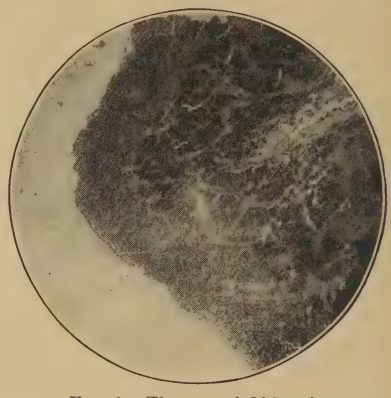


Fig. 4.—Thymus of fifth pair.

condition and the more serious the morbid reaction observable in the paired couple. A change was also found in pairs of animals of the same sex and in those of opposite sex which, united at an early age, seemed to endure the new state without resenting it. The thymic alteration was of the same type, except in degree, in all these instances, and differed from the usual modifications of this organ in infections, in vagotonia, and after exposure to the x ray, having however, a certain point of contact with its physiological involution as manifested in advanced age.

A characteristic of these thymusses is the rarefaction undergone by the small round lymphocytic cells (the socalled thymolymphocytes) of the gland, together with the enormous invasion of plasma cells. The rarefaction of thymolymphocytes does not appear areas of scarcity of the cortical cells appear at the outset (as is seen in the tenth pair, sacrificed on the fourth day of parabiosis) there are present in them numbers of plasma cells, mingled with the greatly altered thymus cells. These are seen first in the severed connective tissue vessels of the cortex and seem to accumulate in the areas of rarefaction, in which they sometimes are found alone, resembling a pure culture. From these areas the rarefaction of the round lymphocytes extends to the whole cortex, which little by little becomes literally invaded by plasma cells.

Figs. 2 and 3 show a lobule from the thymus of one of the twelfth pair, which died the day after the operation (Fig. 2 is slightly enlarged; Fig. 3 more so, up to the eighth power). The rarefaction of thymo-

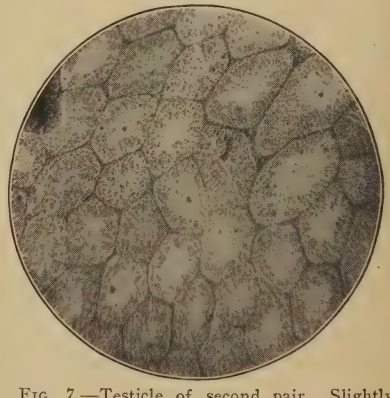

Fig. 7.—Testicle of second pair. Slightly enlarged.

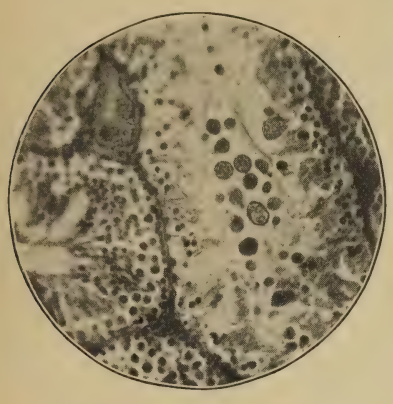
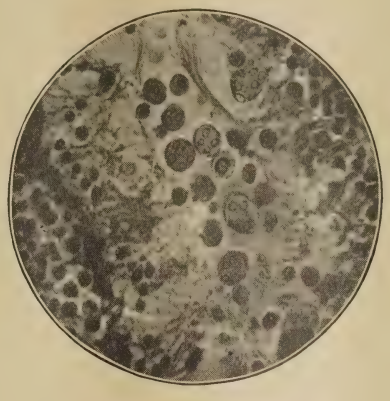
uniformly in the cortex, where, it is to be noted, groups of them separate the glandular structure from the external medulla, but the process begins at certain points in round or oval areas by a progressive change in these elements. They increase, becoming paler and oblong, their limited protoplasm tending to blend with the nucleus, which soon loses its ready lymphocytes in the gland is extreme: the cortical and medullary zones are no longer distinguishable; on the right side of the figure there is a moderate invasion of plasma cells, while on the left they appear in the tissue like a pure culture. The vessels are widely dilated.

A similar appearance was found in the thymus of

one of the fifth pair, sacrificed on the thirty-first day, although the animals, especially the male, exhibited an appearance of complete health. Fig. 4 shows the cortex depleted of cells and invaded by plasma cells, which are massed at the right in pure culture.

In some cases we observed that the areas of rarefaction and degeneration of lymphocytoids progressed to extreme cytolysis, to the formation of detritus and necrotic sequestra in the interior of the cortex, while the plasma cells were clustered near by. An example of such an appearance is seen in Fig. 5, the female of the eighth pair, which died the seventeenth day after the operation. The plasma cells are seen in all their phases; most frequently large and hypertrophic; less often taking on, under Pappenheim, a metachromatic coloring with granulations prevailingly wine red or dull yellow, and with a degenerated appearance; sometimes in certain areas there exists a phase of Unna's granulation, where is seen the same wine red colored detritus of the protoplasm of normal cells (with Pappenheim's pyronine). The plasma cells are always numerous in the connective tissue around the glands and in some cases are diffused throughout the severed connective tissue in the neighborhood of the submaxillary glands. It is difficult to decide from these indications whether these come in reality from the vessels, as many think, or arise locally through the favorable conditions found here. It may be both phenomena will prove to be freely produced locally by the plasma cells held in the connective tissue meshes of the gland.





FIGS. 8 and 9.—The large round bodies, shown in Fig. 7, greatly enlarged.

FIG. 10.—Testicle of second pair.

After the thymus, the glands most decidedly affected by parabiosis are those of sex. Their behavior is, however, very variable and serves as an index of the greater or less effect incurred by the organism in the new state of symbiosis. In pairs united early, as was the seventh pair, and bearing the condition well the structural modifications of these glands are slight or may not appear at all on histological examination. In all the others they are more or less pronounced according to the duration of the parabiosis and to individual reaction. In some pairs, such as the ninth, animals of about six months old which died the day following the operation after a series of violent convulsive phenomena, they are most precocious and in these cases the more the testicle has been injured. In other cases, on the contrary, where after a time the female has acquired a decided resentment for the male, greater changes occur in the ovary.

Let us see first how the testicles behave. In pairs of males studied not longer than two months after

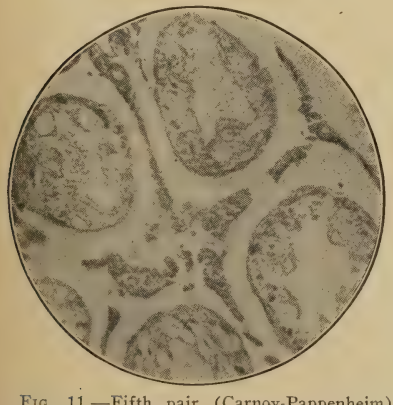


FIG. 11.—Fifth pair (Carnoy-Pappenheim) showing tubular degeneration.

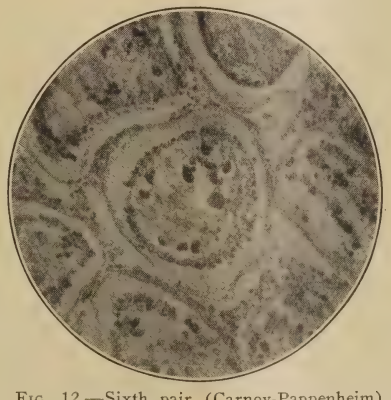

FIG. 12.—Sixth pair (Carnoy-Pappenheim), showing tubular degeneration (much enlarged).

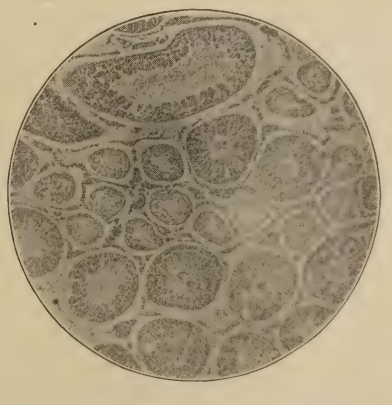

FIG. 13.—Second pair (Carnoy blood alum).

operation they are found normal or with few alterations of the kind described below. In heterosexual pairs a high percentage occurs of early alterations, some of them exceedingly early. Such modifications seem to follow a uniform pathological course.

One of the early phases, which was manifested, for instance, in the ninth pair twenty-four hours after operation, is that photographed in Fig. 6. The greater part of the tubules are normal with the seminal series well differentiated. But there are numerous tubules in which are seen abnormal cells, generally located in the second zone among the spermatocytes and derived from the first division of spermatogones; or else more internally near the centre of the lumen, differentiated by being a little smaller than the spermatocytes of the first division and a little larger than the spermatids, and by having an intensely colored protoplasm and a pycnotic nucleus also intensely stained, homogeneous in its mass coloring (Fig. 6), and no longer displaying chromosomes in the nuclei of neighboring cells. In some other specimens of this type the nucleus is not a single mass, but may be divided into two groups of chromatic substances.

These cells, the darkest and most homogeneous in the microphotograph, represent the first stage in the alteration of spermatocytes. They are encountered in fact in the testicles of pairs which have survived a considerable time and which present alterations and highly complex degenerative forms. In the latter, as in the first (twenty days) and second couple (twelve days), are found cells which seem to belong to the spermatocytes of the first and second order with nuclei in various phases of degeneration, devoid of chromosomes and having in their place either a single chromatic mass or a few minute particles; while in others the nucleus is joined with the protoplasm in a single rounded mass (stained red by pyronine).

Besides these cells, there are other forms characteristic of these testicles, corresponding evidently with those described by Matsuyama in various subjects of parabiosis and called by him giant cells (*riesenzellen*). This is markedly so in a testicle of the second pair, in which the male died on the twelfth day after operation. In Fig. 7, slightly enlarged, we see in many tubules, large bodies, round in form, derived, it may be, from the basal series, appearing at the centre or, greatly enlarged, in Figs. 8 and 9. In these enlargements of the preceding figure these forms seem to result from a protoplasmic mass containing within it numerous small round cells, clear at the centre, with edges deeply stained by basic colors, and of the size of spermatids. In some fields we counted as many as thirteen of these giant cells whose protoplasm is clear and stains feebly with acid stains (red with eosin and yellow with picric acid) and becomes greenish with methylene green. In all probability these formations represent degenerated spermatocytes or degenerated spermatids enclosed in a protoplasmic mass of spermatoblasts. In fact, in some of the tubules of these testicles such formations are not rounded and situated in the centre of the lumen, but oblong, ragged, and located near the periphery in the situation of spermatoblasts, where normally, at this stage of the evolution of the tubule, ought to be found groups of spermatids in process of transformation into spermatozoa in the centre of protoplasmic masses of spermatoblasts (Fig. 10). Here instead, owing to various local toxic conditions, the normal evolution of spermatids into spermatozoa is no longer taking place, but the final elements of the seminal series are undergoing degeneration, so that it is difficult to decide whether they are spermatocytes of the second degree or spermatids enclosed in protoplasmic masses of spermatoblasts, which are detached from the wall and lie in the lumen in the form of a rounded body, where they go to final degeneration.

Tubular degeneration furthermore proceeds beyond this stage of giant cells. Spermatogones cease to be produced, while spermatocytes and spermatids, no longer evolving into spermatozoa, pass in process of degeneration through the various phases of pycnosis, of chromatinic fusion, of cellular lysis, until nothing but detritus remains in the tubules, consisting of chromatin masses in the form of extensive deposits of protoplasm resembling cellular remains without nuclei, so that every morphological element has disappeared and the tubules are reduced to the connective tissue membrane of their own walls with rarely a Sertoli cell remaining. These phases may be followed in Fig. 11 (the fifth pair, whose male was killed on the thirty-first day) and in Fig. 12 (the sixth pair, killed the sixty-fourth day), enlarged to the eighth power; further in Fig. 13 (second pair at twelve days), slightly enlarged, where is seen, interspersed among normal tubules, a succession of atresic tubules devoid of cells of the spermatic series. (These are from the same testicle as Figs. 7, 8, and 9.)

(To be continued)

Historical Medicine

Toothache Three and a Half Centuries Ago*

THE HONORABLE WILLIAM RENWICK RIDDELL, LL.D., F.R.H.S., &c.
Toronto

Scientific dentistry is but of yesterday, but Adam had the toothache, at least every generation of his sons has had: and it may be of interest to know what the best men in olden times thought of it.

In Nancy, in 1572, was born Nicholas Le Pois—the plebeian name Le Pois, the pea, he latinized to Piso—educated in Paris under Jacques Dubois, who latinized his own name to Jacobus Sylvius and became a famous writer on semeiology. Piso advanced in knowledge of medicine as it was then understood and, in 1578, was appointed physician to Charles III, Duke of Lorraine. In Frankfort, in 1580, he published a ponderous folio *De Cognoscendis et Curandis Præcipue Internis Humani Corporis Morbis* . . . which was a compendium of all that was known and guessed of medical science—*de omnibus et quibusdam aliis*. He died in 1590. The celebrated Herman Boerhaave nearly fifty years after his death edited it, adding a preface, and published it at Leyden in 1736; it was again reprinted at Leipsic in 1766, in two volumes octavo.

Whether Boerhaave deserves the reputation which he has of being the most famous physician since Galen's time, everyone must judge for himself; but it is certain that he was a man of great ability, learning, diligence and candor—"a great savant, physician and man." He was a real eclectic, taking truth wherever he found it—from regular or quack, Methodist, humorist, iatromechanic, iatrochemical, iatromathematical, or spagyrist—and besides, he wrote good Latin which all physicians of his time and even a few of ours, could not accomplish—I have heard it suggested that a dentist here and there might fail. Not least of his merits, he was the first to establish permanently the clinical method of instruction, without which modern medicine would be lost.

I use the Leipsic edition of 1766 and confine myself to toothache contained in Chapter xlviii of the First Book—*De dolore dentium.* Although Piso in this work cites more than forty authorities from Hippocrates down, in this Chapter he is to a certain extent "on his own." He leaves aside the other affections of the teeth—projecting (*exerti*) *or worn* (*atteriti*); set on edge by cold or acid food, blackened from lack of cleansing, or livid from sweet and hot food, and crude and crapulous expiration; loose and wobbly (*vacillantes*) from external force or lax alveolus—the author attacks at once toothache because it is the most serious and is to be considered among the greatest tortures (*maximis tormentis*).

"Serious pain of the teeth is called odontalgia from the symptom and the part affected. The part affected is believed by most, if not all, to be manifold. For either the body of the tooth itself is afflicted, as there is no doubt that the teeth (although they are bones) can feel and suffer; or it is sometimes the nerve, which is a branch of the third pair distributed to every tooth and lying at their root. Not seldom the gums are inflamed. But a learned man who lived in our time thought that the nerve alone has any sensation and accordingly alone feels the pain. He says that the tooth suffers because the nerve is suffering, just as a man sees, not the whole body seeing but the eye only. . . . Others say that the tooth seems to feel and suffer because it receives a part of the gustatory nerves of the third pair—the nerve lies at the root of our tooth and so we believe the tooth itself suffers pain."

But the fact that when the tooth is extracted some part of the pain remains, shows that the tooth does not bear the pain; and if it is extracted the nerve breathes more freely, as it is neither stretched nor pressed by the tooth. But enough of the part affected.

The affection is itself the symptom and, as in other affections, it follows some want of health (intemperies). . . .

To speak briefly as to the causes. "If the abnormality is a hot cause the result is inflammation, but the gums rather than the substance of the tooth itself or the nerves are affected. If the fluxion is cold it is chiefly from vitreous phlegm and the pain is most severe."

The author now after the fashion of medieval physicians indulges in a page or two of philosophical disquisition on *calor, siccitas, humiditas, destillitio, humores, defectus, redundantur,* etc., which we may pass over as well as the *prognostica*—and come at once to the *curatio,* treatment.

"If the pain arise from heat, ptisanes are to be taken, gruel (alica), lettuce, cucumber and the like, to be used in moderation and softened lest the teeth should be irritated. Patients are to abstain from wine and use water, in which has been decocted coriander or cinnamon seed . . . nor should they do what so many do, eat the hottest foods and drink the coldest wine or water; that excites the most severe pain, it rots the teeth and ruins them. Let them avoid sweet food, as honey and sugar as well as fats and milk. It is wise to cleanse the teeth . . . and wash them with wine. Let them also avoid acid and tart foods and everything tainted. Every effort should be directed to keeping the teeth from decay. Although such directions are common to all diseases, it is well to give them here before descending to the remaining treatment of this affection from heat.

"To put it tersely, frigids are to be exhibited but not frigid in excess—for the teeth are injured by the excessively frigid, of course because they are themselves so frigid and wholly bloodless. It is to be observed, too, that when the gums are affected the remedies are to be applied to the bare places affected which are free from all kinds of pungency, whether from the moderately acid or of the earthy character. Consequently they shrink from vinegar as from a sharp and hostile sword: it corrodes the

*Written for the Academy of Dentistry of Toronto.

gums by its own acidity. The most soothing thing for them would be asses' milk when they are very painful and inflamed. And pimpinella triturated and applied helps a swelling of the gums.

"Where the teeth alone are affected or the nerve pellicles along with them, then together with these healing medicaments we add those which in their own substance consist of tenuous parts by which the force of them is carried deep within . . . and for a mouth wash, we prepare a decoction in white vinegar of root of halicacabus, aizoon, portulaca, perdicium and licorice. It is helpful to hold in the mouth a decoction of violets in wine.

"If there is a sensation of intolerable heat, use is to be made of hyoscyamus leaves or seed of garden pepper or lettuce seed decocted in white vinegar; oil of roses may be held in the mouth or oil of myrtle mixed with a little white wine: and the head should be moistened with the same oil of roses and it should be dropped in the ears. So too, a decoction of earthworms in oil is to be dropped into nearer ear; and a decoction of them with the oil of roses or of myrtle or oil prepared from the nymphæ and pepper should be used as an unguent on the external parts adjoining the aching tooth."

Having now disposed of the treatment of odontalgia *ex caliditate,* the doctor proceeds to the treatment of that arising *a causa seu intemperie frigida,* from a cold cause of indisposition.

"If there is a simple toothache from frigidity, the food should be ptisanes with pulegium or with rue; or pepper should be added after they are prepared. So, too, gruel of spelt or petroselinum. The drink should be wine but in moderation. For a mouth wash, a decoction should be made in vinegar or wine of origanum, calaminth, hyssop, dictamnus, satureia. Moreover a decoction of veratrum niger eases pain arising *a frigiditate:* in the case of those on whom, sensation is quickly responsive, these decoctions should be made in posea. A decoction of fat woods such as tars or pitches is also helpful—these tars may be boiled n oil. It is of advantage, too, to moisten the head with oil of camomile, anise, iris or rue—as also the external part near the aching tooth. Castoreum decocted in oil should be dropped in the ears. Suffitus from the tooth of a dead dog is recommended, the smoke being taken into the mouth, and then the dog's tooth itself burnt and rubbed up in a little vinegar is to be held, hot, in the mouth. By reason of the special property of its whole substance the castoff skin of a serpent cooked in wine or vinegar is helpful, the same baked and ground up applied to the tooth with oil is also helpful."

Now the author deals with the treatment of the third kind of toothache—that arising from humidity.

"If the teeth are affected from humidity, the diet should tend to dryness with daily abstinence from food. The food given should be such as can be supped, gruel, bread moistened with soup, fine wheat flour, rice, polenta mixed with honey water, millet, lentils, the drier mountain birds, of vegetables, cabbage and the like. For drink, honey water, or water with a little wine added.

"During the pain, the place should be fomented with millet and salt. Mouth washes should be exhibited, astringent, drying or salt, unless the gums are also affected. Consequently we exhibit green olives decocted with tart vinegar and alum mixed with vinegar; in like manner, pomegranate rind and calyx, myrtle berries, balaustia, olives, blackberry leaves, cypress pills, the root of the wood sorrel; and anything which has by nature an acid quality if you concoct it with a little vinegar or wine is helpful if the mouth is washed with it. No little helpful is an ointment made of diamoron confection particularly if it has powdered alum added—or an ointment made out of the juice of nuts: so, too, the dried root of cinquefoil and stag's horn.

"If the teeth have become loose from old age, powdered alum ground up with troglodytic myrrh is helpful to them."

Now comes the fourth class—toothache *a siccitate,* from dryness.

"If the pain arises from dryness, the proper diet will be barley water, morsels of bread, moistened with chicken soup, cucumbers, mallows, soft boiled eggs and whatever food is suitable for patients that are deficient in moisture. The drink should be light wine diluted with water. Sharp and acid medicaments are to be avoided . . . least of all should astringent and moderately moist washes be applied such as hot water by itself—steam from water should be applied with a sponge.

"A mouth wash should be prepared from a decoction of bran or licorice or mallow—or from barley water or starch diluted with sapa or hot water. Asses' milk administered by itself is very useful.

"So far we have been dealing with the treatment of simple indispositions; however, if they are of mixed origin it is quite easy to discuss the treatment of such mixed diseases. In those indispositions which consist . . . in an excess of humors of course (palam) the first thing to do is to reduce the redundant humor by proper purgation . . . then treat the disease. When it happens that toothache makes its appearance from an excess of humors and a redundancy of blood, this should be evacuated by venesection of either the humeral or the median vein. That vein should be cut which has reference to the locus of the affection; and if it be necessary, the vein under the tongue may be cut or cupping glasses applied to the scapulae. If anything prohibits bleeding, reduce the superfluous humor by moderate and slender diet."

Now come topica, the topical application. "The body as a whole being evacuated, to the aching teeth are applied these things that are repressive and repellent and, afterwards, those that are partly repellent and partly discutient. There are, indeed, few diseases that call so much for repellents; and these are the very ones which arise from a minor cause. Consequently we are often obliged to mix discutients from the first—or according to Galen, a little later.

"If the pain arises from inflammation of the gums, the most useful remedy is lentiscus oil, retained in the mouth—it is not nauseating, it is repellent without unpleasantly acid taste and discutient without mordacity. Too strong astringents are to be avoided, from which the parts would suffer as from a contusion, just as from acids like from erosion—the moderate are to be adhered to—after lentiscus oil, asses' milk, sapa or the juice of dates. The decoction of stonecrop is also effective. For affected in their proper substance or the underlying nerve, the strongest medicaments are to be used.

"The teeth are to be washed in vinegar in which oak galls have been decocted or the root of the halicacabus or myrtle leaves; in process of time, discutients are to be exhibited such as hyssop, melilot, fenugreek, althea, pulegium, origanum.

"Stupifacients should not be employed, except in the last resort and except in case of excess of hot humors. If there should be an excess of bile causing erosion of the teeth, the condition of the whole body not alone of the head is to be looked to and purgation by cholagogues resorted to. . . . If there should be an excess of frigid humors, and the toothache then arise, after an evacuation of them from the whole body including the head—in which case it is well to use antiphlegmatics which have the force of moderate astringents and strong discutients and should be administered hot, such as rue, polium, pulegium, origanum, hyssop, or caper root decocted in vinegar or wine—it will be advantageous to use the same treatment as for toothache *ex frigida aut ex humida intemperie,* from cold or humid indisposition."

(To be continued)

Contributors to the Science of Medicine

Sir Charles Bell

Charles Bell was one of that band of workers, and especially, perhaps, clinical workers who helped to make the name of Edinburgh famous throughout the world for its medical and surgical school. Without the enormous clinical material of London and other large cities, Edinburgh has more than held its own in the realm of medicine and surgery. In this country no British school of medicine and surgery has a higher if so high a name as Edinburgh and, as said before, this is largely due to the fact that there have been trained and developed in it some of the leading lights and teachers of medicine and surgery, and that chiefly on this account among those outside Great Britain it has gained and maintained a name unexcelled in Europe. Many of the great surgeons and physicians of this country of former times received their training at Edinburgh, Ephraim McDowell, for instance, although it must be said that his original views were developed and put into practice in his own country.

Charles Bell and his elder brother, John, were among the great surgeons of Edinburgh. Charles was born there in 1774, the youngest son of the Rev. William Bell, and received the first part of his education at the High School, Edinburgh. John, his elder brother, was already a celebrated surgeon, and Charles, who had early turned his attention to anatomy, assisted his brother in his anatomical lectures and demonstrations. Even before he had become a fellow of the Edinburgh College of Surgeons, he had published the first part of his plates of dissection.

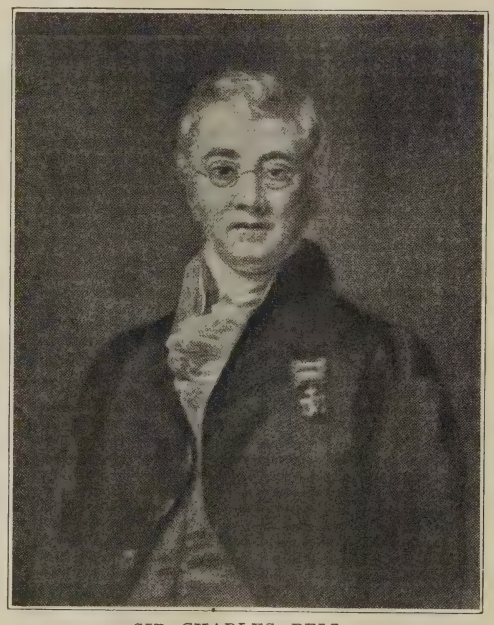
In 1799 he was admitted a member of the Edinburgh College of Surgeons, and immediately after was made one of the surgeons of the Royal Infirmary, then the only hospital in Edinburgh, where he showed remarkable skill as an operator. He was one of the first to use the knife in lithotomy, and on the first occasion on which he did this operation at the hospital succeeded in extracting the stone in two minutes and a half, to the astonishment of those who had been accustomed to witness the protracted suffering of the patient under the operation with the gorget.

A somewhat trivial occurrence was the cause of Mr. Bell leaving Edinburgh. A controversy arose with regard to the proposed repeal of a regulation, under which all the fellows of the College of Surgeons in turn were allowed to operate at the infirmary. These differences of opinion were embittered by imputations on the purity of the motives of the senior members of the college and by the insinuations that they were actuated by unworthy jealousy of the younger men. The dispute became so acrimonious and abusive that the profession of Edinburgh was split into rival camps led on the one hand by the great Dr. Gregory, whose name has lived largely by his powders, and on the other side by John Bell. It developed into a personal altercation in which the time and brains of two of the most distinguished medical men of Scotland were wasted in sarcasm and invective. The only redeeming feature of the situation was that the rival effusions of the two chief contestants were embellished by wit and fancy.

The dispute so got on the nerves of Charles Bell, who naturally as the brother of the leader of the young party became involved in the controversy and in the prejudices inseparable in so restricted a society as that of Edinburgh, from the rancorous system of professional partizanship, that he left Edinburgh for the wider field of London. His idea was to lecture on anatomy and surgery. The task he had set himself was difficult. At that time the lecture rooms of London were occupied by anatomists of the first rank, among whom were Cline, Astley Cooper and Abernethy. But Bell had full confidence in his knowledge and qualities as a lecturer and was not discouraged. This confidence was justified by the results and from the outset of his London career he took his place on a footing of complete professional independence and equality.

At this time he associated himself with Mr. Wilson, F.R.S., in the school of anatomy in Great Windmill Street, rendered famous by John and William Hunter. Bell upheld the great traditions of the school. His mode of lecturing was adapted admirably to engage and keep the attention of pupils. His style of lecturing, when he had ceased to demonstrate from the subject before him, partook more of the nature of animated and close reasoning, delivered by a person intent on carrying conviction to the minds of his hearers, than of those uninteresting details of minute facts, which too often rendered lectures on anatomy vapid and tiresome to the student.

Bell's lectures were of the highest grade resembling those discourses which he afterwards delivered in the College of Surgeons of London. In the year 1812 Bell's reputation was established so firmly in London that he was elected a surgeon to the Middlesex Hospital by an open poll. In this hospital he delivered clinical lectures. Bell had long been anxious to study the surgery of gunshot wounds. The first occasion upon which he was enabled to gratify this desire was in the year 1809, immediately after the battle of Corunna, when the wounded hurried home in transports were landed on the southern coasts of England, little having been done to them in the meantime. An opportunity was thus presented of becoming acquainted with the peculiarities of wounds received in battle such as rarely had occurred to a surgeon unconnected with the military service. In order to do this Bell had to relinguish his London engagements. As a result of knowledge thus acquired he published an *Essay on Gunshot Wounds,* which he added as an appendix to his *System of Operative Surgery.*



SIR CHARLES BELL

The second occasion on which Bell took advantage of a similar opportunity was after the battle of Waterloo. He and his brother in law, Mr. John Shaw, were the first surgeons from England who arrived in Brussels. This journey was undertaken mainly for the purpose of obtaining cases and sketches to illustrate further the subject of gunshot wounds but on finding himself surrounded with so much suffering he offered his services wherever they might be most needed. At that time, and after such a battle, the ordinary supply of skilled aid was necessarily inadequate and his offer was accepted gladly. He was at once placed in charge of a hospital, and, for three successive days and nights, was engaged incessantly in dressing wounds and operating on the injured. He gave surgical aid to three hundred men and the drawings with which he was enabled to enrich his collection have been referred to as the finest specimens of water colors in the English anatomical school. It has been suggested that to this expedition we owe, perhaps, the volume in which Sir Walter Scott depicts the same scenes, as Lockhart in his *Life of Scott* states that a letter written by Mr. Charles Bell to his brother John laboring under the excitement of the scenes at Brussels made so deep an impression on Scott that "When I read it," he said, "it set me on fire," he immediately departed for Brussels and the book which appeared afterwards under the title of *Paul's Letters to his Kinsfolk* was the result.

In 1812 Bell became a member of the English College. A few years after he was appointed professor of anatomy and surgery at the College of Surgeons and then a member of the Council. He was an especially felicitous and able lecturer.

The Earl of Bridgewater, one of the most remarkable men of his generation, famed alike for his scientific attainments, for his lavish outpouring of money, with which he was more than plenteously endowed, for scientific and utilitarian purposes and for his eccentricities, left a sum of 8,000 pounds in trust to the president of the Royal Society of London with the object of rewarding the author of a dissertation on the power, wisdom and goodness of God as manifested in the works of his creation. The president shrank from the responsibility of choosing a person best suited to fulfill the terms of the bequest. He therefore took counsel with the Archbishop of Canterbury and the Bishop of London and together they determined to divide the sum left at their disposal among the writers of eight essays, illustrative of the subject proposed. In his will the Earl of Bridgewater had expressed a desire that the power and construction of the human hand should be embraced in the dissertation and when Bell learned that he had been selected as one of the essayists, chose that as the subject of his essay. The essay was not only the best contribution on the hand ever made but bore directly upon and fell in with the purpose of the testator.

The School of Great Windmill Street, over which Bell presided and in which school such men as William and John Hunter, Baillie, Cruickshank, Thomas Wilson and Brodie had taught, had come to be regarded as the portal of entrance to surgical distinction in the West of London, passed out of existence. This was owing to the establishment of the University of London, within ten minutes' walk from Windmill Street, and to the fact that the Middlesex Hospital was situated not far away. As somewhat of a compensation for the large pecuniary loss suffered by Bell through the closing of his school and as a reward for his conspicuous abilities, the governors of the University of London placed him at the head of their new medical school.

In the year 1836, at which period Bell's reputation, chiefly in consequence of his discoveries connected with the nervous system, had become international, he was invited to the chair of surgery in the University of Edinburgh. He continued his work in his native city with as great success as in London.

Bell was an able writer. His first publication was *A System of Dissections.* Then followed *A System of Anatomy* by John and Charles Bell. He was an accomplished draughtsman and painter and illustrated the preceding work with *Engravings of the Arteries.* This was followed by *Engravings of the Brain* and by *Engravings of the Nerves.* He also published *Essays on the Anatomy of Expression in Painting,* in which he pointed out the importance of a knowledge of anatomy to the artist. In 1811 he printed for distribution among his friends a small essay en-

titled *Idea of a New Anatomy of the Brain.* In 1813 he published a volume of *Engravings from Specimens of Morbid Parts.* In 1816 he commenced the publication of *Surgical Observations,* and in 1819 an *Essay on the Forces Which Circulate the Blood.* In 1820 *A Treatise on the Diseases of the Urethra, Vesica Urinaria, Prostate and Rectum* was published. His most important contributions to scientific medical and surgical literature were those on the nerves concerning which he made some important discoveries.

The Middlesex Hospital in the time of Bell was the refuge, as it is now, of large numbers of persons suffering from malignant disease, and he wrote an article in the *Medico-Chirurgical Transactions* (Vol. 12, p. 213) "On the Varieties of Diseases Comprehended Under the Name of Carcinoma Mammæ." This article, in view of the great interest now taken in diseases of this character, may be referred to. As said before the cancer ward of the Middlesex Hospital afforded to Bell great facilities for observing this disease. Its intractable nature, the number of unsuccessful operations for its relief, and the natural dread entertained of the knife, especially when it was considered that there were no anesthetics, tended much to throw these cases into the hands of empirics, who without a knowledge of pathology and destitute of principle but guided solely by avarice, took every advantage of suffering humanity and held out to the ignorant the possibility, nay the certainty of a cure without resort to operation. Bell states that "by much the larger portion of patients received into the cancer ward of the Middlesex Hospital have spent their last penny; and, what is worse, they have lost that precious time in which they might have been cured in attendance on a set of the most unfeeling wretches, that ever disgraced a country." Bell gives a history of carcinoma, he describes other malignant diseases, different in certain respects from true carcinoma, but of the same nature. He then considers the character and changes of the more common form of the disease, he gives instances of the mistakes liable to be made in treatment and by marking particularly the changes to which it is subject he points out the deceits that are practised on public credulity. This article on cancer written by one of the keenest clinical observers who ever lived and who possessed an unrivalled knowledge of anatomy, surgery and physiology should be read by those who have had experience with malignant disease at the present time. It will be found probably that clinical knowledge of cancer, as expressed by Bell in 1820 or thereabouts, was much the same as nowadays. He recognized the fact that surgery was the only possible means of cure or of lengthening the term of life. Authorities now say much the same thing.

Bell had a profound influence on the surgery of his time and over and above that was an original thinker. His discoveries with regard to the nervous system alone entitle him to a high place among the contributors to medical science.

He died at Hallow Park near Worcester on Thursday, April 28, 1842, in his sixty-eighth year. His epitaph, written by Lord Jeffrey, reads as follows: "Sacred to the memory of Sir Charles Bell, who, after unfolding with unrivalled sagacity, patience and success, the wonderful structure of our mortal bodies, esteemed lightly of his greatest discoveries, except only as they tended to impress himself and others with a deeper sense of the infinite wisdom and ineffable goodness of the Almighty Creator."

The Viper in Therapeutics.—*L'Echo Médicale des Cevennes* publishes an interesting article by H. M. Noël on the viper in ancient therapeutics. We quote a few paragraphs: "The flesh of the viper, eaten fresh, roasted on the grille, was used as an infusion in wine, in syrup, in jellies, and in soups, or as a powder after desiccation. The head dried and hung around the neck of infants was supposed to prevent convulsions. According to other authors, the head wrapped in linen and hung around the neck was an excellent remedy for quinsy. Ashes of viper skin cured scurvy if the patient was frequently rubbed with it. The ashes of a whole live viper, placed in an earthenware pot with two ounces of fennel juice and a grain of incense, covered and well packed in clay and put in the oven to bake, were most efficacious in preventing cataracts and 'obfuscation' of the eyes, whether applied directly or in the form of eyesalves. Galen claims—and Dioscorides rightly ridicules him—that the flesh of vipers ingested produces pedicular disease; meanwhile he himself writes that the Egyptians were accustomed to eat vipers and other serpents just as they did eels.

"Cardan lays claim also to having cured ulcers of the lungs with the same drug, of which he slightly changed the formula. But it was especially for affections of the skin that its use prevailed throughout many ages. It was employed in Egypt, Greece, Rome for elephantiasis. Jean de Vigo, surgeon to Pope Julius II, mixed it with mercury, and it reappeared in the composition of the famous salve which bears its name. Of this salve the oil of vipers mixed with that of toads and earthworms, cooked alive, was the basis. At the time when syphilis had just made its appearance in Italy and the epidemic was at its height, Vigo considered it a skin disease and treated it as such. The use then made of mercury was only a survival of the theories of the alchemists. Van Helmont, who was a fervent disciple of the alchemists, brought into vogue medicaments produced by chemical action, which did not prevent him from applying the most bizarre remedies. This explains his account of his having cured a peasant afflicted with dropsy by having him wear a girdle of vipers.

"Ancient therapeutics thus derived many remedies from vipers, such as ointment, volatile salts, wine and bouillon of vipers, which were considered tonics and bracers. The body of the reptile, after having been dried and pulverized, was infused in the wine and used also as a sovereign remedy for bloating or flatulence in animals. The oil served as a panacea for sprains and bruises; old coquettes anointed their faces with it to restore youth."—*Translated from Aesculape.*

HEALTH AND HEREDITY

We seem particularly prone these days to overlook heredity as a factor for health. Perhaps it is well not to make too much of it lest we become unduly fatalistic as to what may be done for the race, and heaven knows we have, in past time, been sufficiently of this mind in this matter.

We are not to mistake, however, the point as to where heredity begins and blame things on our ancestors which do not belong to them. Effects of intrauterine conditions, of misfeeding of the mother and malnourishment of the child, are not hereditary faults, though both parents may be somewhat to blame for the results. Certainly family traits preceding conception must be considered and the germ plasm may be modified up to this comparatively recent date.

Health is the condition of bodily perfection of structure and activity resultant from the influence of environmental conditions upon the product of conception. These conditions are most varied and powerful, yet we do not know how far they affect the new assortment of living matter. Certainly after the first few months heredity is strongly assertive, and we can assuredly say that "health is a markedly hereditary characteristic."

If physiologically we are as unchanging as we are anatomically, health, aside from effects of accidents (including infections), changes but slightly, for our features, whether of face or of form, change very little indeed; the mole or the nevus remain where and as they were, one eye continues to be higher than the other and one foot longer than the other until we are done with feet and eyes, nevus and mole.

Just how far we can combat hereditary tendencies to disease or just how much we ought to attempt to do so no one knows.

Hereditary physical and mental traits on which health depend are no doubt the result of habits of individuals stretching back through generations of them, and we can only infer that by attempts at modification of habits in individuals of this generation we may possibly modify its germ plasm for the better.

As a rule, however, we do not have the possessors of this plasm coming to us for conditions of evident hereditary origin until after the time for producing a new generation. Our chief hope of such modification would seem to rest, then, in trying to improve the health habits and the health information of young people, in the belief that it may influence their later health and the health of the future generation in some small degree.

Heredity undoubtedly more than aught else limits the length of life of the individual. There is ample evidence of this. Human life, on the whole, is being lengthened, but this is chiefly true of humanity in mass, in the longer survival of the young rather than in a lengthening of the older lives. Strange, that in that minute mass of mysterious matter from which we grow the number of our days is already roughly recorded.

THE LEAD TREATMENT OF MALIGNANT NEOPLASMS

The lead treatment of cancer during the comparatively short time during which it has been before the public has been discussed more fully than any other treatment of the disease previously. Opinions on the method have varied considerably and therefore its further discussion at the recent meeting of the British Medical Association at Nottingham helps to elucidate a somewhat vexed problem.

Dr. J. G. Adami, of Liverpool, read a paper by Dr. Blair Bell, the originator of lead treatment of malignant growths, who was prevented from attending by illness, in which it was pointed out that it was more essential to discover the nature of the cancerous process itself, the character of the change from normal growth to cancerous development, than to discover the socalled causes which were really predisposing factors. There were many extrinsic and intrinsic factors which could produce the precancerous condition.

These included radiation of various kinds, heat, trauma, infection, toxemias, and senescence, all of which reduced the vitality of the cell. It seemed probable that the metabolic disturbance leading to the change might be oxygen starvation. The ancestral type to which the cell sought to return in the reversionary process was that of the chorionic epithelium, which had the power to invade and erode bloodvessels in its search for nutriment. It might be expected that cells of the chorionic epithelium would resemble malignant cells in structure, function, and chemical composition, and in toxicological affinities.

The investigation of this working hypothesis undertaken at Liverpool had presented a formidable array of problems. In seeking for a therapeutic agent lead was chosen because of its action on chori-

onic epithelium, but to have found that chorionic epithelium and cancer cells were similar in nature and that lead was specifically toxic to both, was not enough. The results must be improved and rendered consistent, and patients must be protected against the harmful effects of lead poisoning.

Dr. Francis Carter Wood, of the Crocker Institute for Cancer Research, Columbia University, took part in the discussion and described the results of his investigations into the changes produced by lead in large transplantable tumors of rats. He concluded that the first effect of the lead was a thrombosis. The surrounding tissues then underwent change, owing to the toxic action of the lead upon them. The tumors were not cured in all cases, but these tumors in the rat were more malignant than in man. Lead did not exert toxic influence on them, and cures had occurred.

A valuable contribution to the discussion was by Prof. G. G. Glynn, of Liverpool, in which he told with as great accuracy as is possible at present the existing situation as regards lead treatment of malignant neoplasms. He said that the following conclusions had so far been reached by Blair Bell and his coworkers: There was histological evidence that lead had damaged a very small percentage of the malignant neoplasms examined from patients. It could not be expected that a large percentage would show damage because only a comparatively small number of patients were clinically benefited by the lead. There was a greater tendency to necrosis, and sometimes to a slowing in the rate of growth, so that the malignant cells had time to become more specialized; thus keratinization and the formation of cell nests and goblet cells appeared to be more common.

There was no damage to malignant growths, which was histologically pathognomonic of lead. It most probably acted by increasing the regressive changes which normally occurred to a greater or less extent in all malignant neoplasms. The tendency to thrombosis in carcinoma was no greater; thrombosis in sarcoma might be more common, but it was probably secondary. The absence, however, of any characteristic changes was not proof that lead had no action. If an investigation was made into the effects of arsenic or mercury on chancres or gummata, nothing histologically pathognomonic of these remedies would be found. The effect of lead upon a similar malignant growth varied greatly, even when it was administered under apparently the same conditions. This suggested that the patients' tissues of resistance, using the term in its widest sense, probably played a part in determining the success or failure of treatment, as they did in malaria treated with quinine and in syphilis treated with mercury.

Dr. L. Cunningham, of Liverpool, also emphasized the point that in treating cancer with lead one of the greatest difficulties had been the selection of cases which presented a reasonable chance of being benefited and could at the same time withstand the toxic effects of the drug.

The outcome of investigations undertaken and the results of treatment so far seem to warrant the statement that, to a great extent, lead treatment is still in the experimental stage. The remedy in itself is dangerous and the greatest care must be taken in the selection of patients. In inoperable cases it appears that the treatment is worth the risks attending it as the lead has certainly an action on malignant growths whether it be toxic or tending to regressive changes. It is to be hoped that continued investigations will clear up some of the obscure features with regard to malignant neoplasms and that means may be found of rendering the administration of lead less dangerous and to some extent of standardizing the dose. In the treatment of cancer, as in all diseases, the personal equation plays a great part. The truth of this statement is being emphasized every day.

However, as Bell insists, it is more important to discover the nature of the cancerous process than to discover the causes. Successful treatment is more likely to follow the discovery of the nature of the disease than to follow the discovery of the causes and it is successful treatment, preventive or remedial, that should be the object of all disease investigations.

SOLVING THE DENTAL PROBLEM

"Twenty-five per cent. of the teeth of eighty-five per cent. of children become decayed during school days." There are twenty-five million children of this age. With but one tooth per child filled each year at the rate per tooth which seems prevalent among tooth tinkers these days, we have an annual outlay of some one hundred million dollars, which sum, in a way, is pure waste of good cash, just as the sum paid for replacing bad bricks in a wall is a waste. The latter is occasioned by carelessness, cupidity or ignorance of the brickmaker, but the former only by the ignorance of the toothmaker.

But this is but a drop in the dental bucket, for there are not enough dentists to do all that ought to be done for adults, and it is estimated that there are not more than five per cent. for all work for all ages.

Of course the real way out of this masticatory mess is by the way we got into it, namely, by a return to a good toothmaking diet, nor does this mean that we must go back to the raw foods of our simian forefathers. There seems hope that the nutri-

tionists will help us out in this matter without resort to an animal menu. We would be a considerable day's journey on the way if our present knowledge could be put into practice in the hygiene of the expectant mother and infant. The teeth of animals could be promptly spoiled in the making by upsetting their dietary, and there is no reason why a right setting of the human dietary may not do the reverse.

Leaving the matter of nutrition to the nutritionists, on the result of whose studies we look with the greatest expectation, the workers in the Forsyth Dental Clinic seem to have solved the problem of dental prophylaxis after the teeth are made. They have done so by discovering that the developmental defects in the enamel of the teeth can be detected on eruption and if patched immediately these teeth are practically good for life. The first of the second teeth—the sixth year molars—for some reason (doubtless because they are finished at a time when the resources for nutrition are most meagre) are by far the most defective and otherwise troublesome, and if these can be preserved the other permanent teeth can be readily managed, especially if examined on eruption and any defects made good.

The clinic has been carrying on this experiment in prophylaxis for ten years and has reduced the loss of teeth by extraction from one in every three teeth to one in every two hundred, "the one in every two hundred being from the mouth of a child from some outlying town or district where early attention had not been definitely given."

What Dr. Cross has to say on the subject seems too good to be true.

"In a recent check up of the school children in the Boston public schools, more than ninety per cent. of one thousand children in the ninth grade had four good sixth year molars with vital pulps and nothing but small fillings in organic defects (pits and fissures). If results of this kind can be obtained in a large group of children starting indiscriminately in the first, second and third grades, we may expect a much better showing in any group in which all could be started definitely before their seventh year of age. Teeth treated in this way, unless some serious nutritional condition appears, will last these children during their whole lifetime. It may be necessary to replace some of the fillings, depending upon the thoroughness with which they were originally done, but otherwise the teeth will be serviceable. Teeth in this condition never reach the stage where there are serious complications arising from them, such as the necessity for large fillings and pulp cavities, inlays, devitalizing of the pulp of the tooth and the consequent root canal treatment, with a possible abscess and the focal infection which so frequently results therefrom.

"We should realize that practically all of the conditions and the diseases said to have their origin in the teeth occur in these teeth or from these teeth after the teeth themselves have passed a certain point of soundness. So all the systemic conditions —endocarditis, arthritis, rheumatism and others, so far as the teeth are concerned—can be entirely prevented by this early attention or dental hygiene.

"Treatment at the right age is really the key to success and results in the avoidance of subsequent complications. It is upon this one simple feature that practically all satisfactory results in dental hygiene have been obtained at the Forsyth Dental Infirmary.

"While this early treatment produces such remarkable results, it is not real dental hygiene, for there is something back of these organic defects—the systemic condition causing the defect. This of course is a nutritional factor and is distinctly a medical one. When more is understood about calcium metabolism and fixation, so that some procedure can be carried out to insure the development of the teeth free from organic defects and with perfectly formed enamel and dentine, and the manner of maintaining this good structure is known, we shall then have the actual condition, now artificially attempted, of real dental hygiene."

THE RELIGION OF HEALTH

Health and religion have always been linked. Their relationship, however, has depended on what was meant by religion. The less health they possess, the more religious many people become. Some great saints, like Francis of Assisi, were made so by sickness. A few have been driven by suffering to "curse God and die," but in bodily extremity the most of us cultivate His good opinion most sedulously and even call for prayers in our bodily behalf by those who are supposed to have special influence with the ruler of the universe.

So long as the cause of ill health, and particularly of wholesale sickness in epidemic form, was altogether a mystery which seemed connected with the resentment of the deity (over conduct having nothing to do with him), it was but natural that the chastisement bestowed should be received with resignation and that the deity should seem to have no pleasure in human bodily well being or beauty.

Perceiving the relationship between ill health and religiosity, it became the teaching and practice of the professionally and profoundly religious of more than one faith that the abuse of the body was a means of obtaining a state of grace and of paving our path to paradise.

In ascetic theory and practice, therefore, religion

and health were related more antithetically than sympathetically. High ideals of religious living were far from carrying with them high ideals of bodily perfection, and, since the Christian conscience is still strongly linked with the former, it must be taken into account in all of our health work, private and public, that we are dealing with something for which, by the standards of morality, still dominant, there is no high incentive.

Only a generation ago the president of a leading American university, a minister of the Congregational Church, declared it a sin to look upon the human body with an eye to enjoyment of its beauty or with the intent of improving its defects. If such was the view at the top, then what is to be expected as yet at the bottom of the religious heap? We are making progress religionwise, however, throughout the whole mass of humanity. We no longer sing about wanting to be an angel, which no really sane person ever did wish, though his conduct in the matter of hygiene was often consistent enough. We are not so much intent on escaping hell fire and getting to heaven as on making the most of this present existence.

There is even a tendency in the church to put health first, or at least to correlate it with religion. George Porter, S. J., in one of his letters to a troubled communicant remarks: "As for evil thoughts I have so uniformly remarked in your case that they are dependent upon your state of health that I say without hesitation, begin a course of vichy at Carlsbad." To another he writes: "Better far to eat meat on Good Friday than to live in war with everyone about us. . . . Much of your present spiritual suffering comes, I fear, from past recklessness in the matter of health." This from an archbishop in the twentieth century is the reverse of the attitude of the medieval monk and of the ideas of most nineteenth century preachers of the gospel.

In 1915 Francis Thompson published a little book, *Health and Holiness,* with an introduction by a churchman, in which we read, "Health, I have well nigh said, is Holiness. What if Holiness is Health? Two sides of one truth. In their coordination and embrace resides the rounded answer. It is the embrace of body and spirit, seen and unseen, toward which mortality, sagging put pertinacious, unalterably tends."

If this is the teaching in what has been considered, but which in many ways is not, the most conservative of religious bodies, there is high hope for improvement in the physical aspect of the human race; for only those with high ideals attain to anything in this world, and if religion and health are looked upon as related and the moral practice of one merges into that of the other, the search for the kingdom of heaven and the cultivation of health become identical.

The religion of asceticism laid down certain laws in regard to conduct, the fulfilment, or the nonbreakage, of which made for righteousness and escape from future punishment. Just what was to be done or not done for the attainment of a state of grace aside from the belief in the tenets of the church and attendance on its services has not always been clear, but the care and improvement of the person or of the race has not figured in this moral code. With the development of the religion of health, conduct conducive to health becomes incorporated as the basis of morality in practice of the holy life as well as in the theory of holiness.

Obituary.

DR. J. F. HALL-EDWARDS

Birmingham, England

Another name has been added to the toll of victims of the x ray. Almost all the early workers in x rays suffered severe injuries, many of them suffering mutilation by severe operations for the relief of the pain or malignant ulceration caused by x ray burns.

Dr. John Francis Hall-Edwards, who died on August 16, 1926, near Birmingham, was one of the first and foremost of these martyrs to science and was conspicuous both with regard to the extent of his injuries and for the unflinching courage with which he bore them. He was born on December 19, 1858, and received his education at King Edward's School, Birmingham, and at Queen's College, Birmingham. He obtained the license of the College of Physicians of Edinburgh in 1885 and settled in practice at Moseley near Birmingham.

He was an enthusiastic photographer so that the discovery of the x rays found him prepared to study them with the interest of more than an amateur. In 1899 he was acting as surgeon radiographer to the General and Orthopedic Hospitals in Birmingham. In the South African War he served as surgical expert in x ray work to the Imperial Yeomanry Hospitals at Deelfontein and Pretoria. From this time onward he suffered severely from x ray burns, so much so indeed that after six years of constant pain he had his left arm and the greater part of his right hand amputated. In spite of these disabilities he received a commission as temporary major in the R. A. M. C. on the outbreak of war in 1914 and was appointed consulting radiographer to the First Southern and other military hospitals in the neighborhood of Birmingham. At the end of the war he continued to practise as a radiologist. He also acted as editor of the *Archives of the Röntgen Society* and president of the British Electrotherapeutic Society and was an honorary member or Fellow of various scientific societies, American and British. In January, 1922, he received the Carnegie Hero Trust medallion, with an annuity of $500. He published several books on radiography.

Group of American Physicians in front of Hotel Bristol, Oslo

A Study Tour of Europe in 1926

RICHARD KOVACS, M.D.

New York

The Travel Study Club of American Physicians, organized at the Seventeenth International Congress of Medicine, London, 1913, started on its second European Study Trip on June 12, 1926, when twenty-nine participants sailed from New York on the S. S. *Stavangerfjord* of the Norwegian American Line. The eight days of ocean travel were a pleasant means of relaxation after the rush to tear oneself away from the too well accustomed duties of medical practice and served as an opportunity for the members of the study tour to become well acquainted. Participants hailed from as far as Florida, California, Arkansas, and Minnesota. Dr. Fred H. Albee, of New York, acted as president, Dr. Louis Livingston Seaman, as president emeritus, and Dr. Richard Kovacs as secretary. There were six women physicians among the participants. Daily evening meetings of the study tour were held in a special sitting room, the program of the tour discussed, and informal addresses listened to.

The landing in picturesque Bergen, at the same altitude as Southern Greenland, occurred on the longest day of the year, with the midnight sun shining brightly a few degrees farther north. There was practically no darkness at night, and small print was readable under the bright sky almost up to midnight. For this reason, here and in Oslo, our next station, no street lights are lit from the middle of June until the end of July. The railroad trip to Oslo, the capital of Norway (with its name recently changed from Christiania), along wonderful fjords and over snow covered high mountain ranges, is one of the scenic routes of the world.

NORWAY

Oslo, with a population of about 250,000, is situated along the waters of Oslofjord and surrounded by hills presenting fine vistas. Two days were spent visiting medical institutions. The Ullevaal Sykehus (city hospital) and Baerum Hospital (county) are both situated on lovely grounds and especially the latter offers a wonderful view over the waterfront and wooded hills. They were built at the time of the war boom when, besides the resident population, a great many interned soldiers of the warring nations had to be cared for. Representing the best type of hospital construction, they were very expensive to build and are still more expensive to maintain, much to the regret of the taxpayers, for here, as elsewhere in Europe, most hospitals are maintained by the community at large and their medical personnel are fully salaried city or state employees. The medical men, on the other hand, complain that taxes take away an unreasonably large part of their salaries, the collapse

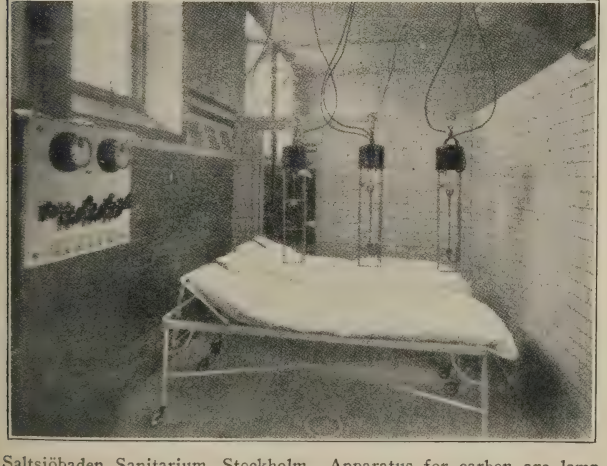
City Hospital, Oslo

of the wartime prosperity having left Norway with a considerable deficit. The individual patients are very well cared for, often in small wards with plenty of window space and sunshine. Besides the usual general departments, we noticed in each hospital a finely equipped institute for physical therapy, usually attached to the medical division. In these we saw the extensive application of carbon arc lamps for general tonic treatments; during the winter months with only a few hours of light and farther north with almost none, a number of conditions of malnutrition, forms of tuberculosis, and neurasthenia develop, which are usually well relieved by artificial light.

The language of medical books, etc., is naturally Norwegian, but in the libraries, laboratories, we found an equal mixture of English and German textbooks. At the University Hospital (Rigshospital) which is a state institution and serves as a teaching centre for the University of Oslo, we were met at luncheon by the members of the Faculty of Medicine, all of whom speak excellent English, like all other well educated Scandinavians.

SWEDEN

A night's ride took us to beautiful Stockholm, justly called the Venice of the North. There is a rich variety of imposing buildings, fine scenery, and hustling life along the edge of its numerous waterways. Its medical institutes are abundant and of high



Saltsjöbaden Sanitarium, Stockholm. Apparatus for carbon arc lamp treatment

rating, with a splendid type of workers therein. The ancient Serafimerlasarattett (Royal Hospital of the Seraphim) is a state hospital founded in 1739, housing about 450 patients. A medical clinic was held by Jakobaeus on his original work in thoracoscopy, and a surgical clinic by Docent Olivecron (brain tumor operation). Professor G. Forssell demonstrated the x ray institute. The hospital serves as a teaching centre for the Karolinska Institute, the medical school of Stockholm, which is situated opposite. Later Dr. Westergren demonstrated his sedimentation reaction of red corpuscles, which in comparison with the temperature curve is of considerable diagnostic and prognostic value in tuberculosis and polyarthritis. There are two quite modern municipal hospitals, the Sabbatsberg Sjukhus, where Docent Josefson made medical rounds, and Dr. Hybbinette, the world famous "singing" surgeon, operated. Dr. Hybbinette's operating skill is, however, at least equal to his Carusolike high baritone. He does not sing at the time of operations, as reported, but entertained

Bispebjerg Hospital, Copenhagen. Main concourse between pavilions

us during and after the dinner given by our Swedish colleagues. The Maria Sjukhus is another fine new municipal hospital, and there Professor Key, the dean of Swedish surgeons, operated. In the Centrallasarett Chief Surgeon Giertz made rounds and operated. In all of these institutions we were impressed by the complete teamwork between the various departments and the efficiency of service from every standpoint.

Among the many special institutes, we saw the radium hemmet (radium home), a model institute for cancer therapy, under the leadership of the internationally known x ray man and editor, Professor Forssell. According to the operability of the case, deep x ray therapy, electrocoagulation and radium are used. A very excellent followup system is in vogue; the state pays for the journeys of the poor patients and the municipalities for the cost of treatment of their own patients. Due to the cooperation of physicians from all over the country, cases are now received much earlier and the results are consequently growing still better. The *Lillahemmet* is a home for hereditary syphilitic children, founded in 1901, and in spite of the newer antisyphilitic remedies, we found still a goodly number of little inmates. There are quite a number of fine children's hospitals.

like the Sachska Barnsjukhuset (Sach's children hospital), the Allmanna Barnhuset (public children's hospital), etc. In the St. Goeans Hospital there is a model department for tuberculosis of bones and joints.

An institute of great interest is the Vin and Spiritcentralen, which is the headquarters for a semistate company for the Stockholm system of alcohol control and distribution. Any citizen provided with a passbook issued after due investigation is allowed to buy a limited amount of spirituous drinks, of any kind, but not more than four litres (quarts) per month, with due allowance for special occasions. With private pecuniary interests removed, and a strict control over manufacture and stocks, this system now in vogue for about ten years has rapidly decreased drunkenness and alcoholism. There is practically no illicit trade, because the law abiding citizen is not deprived of the use of alcohol, once he got over the necessity of getting his passbook, and public opinion definitely supports this system. A glass of champagne from the abundant stocks was tendered to the investigating Americans by the goodnatured State Secretary.

The leaders of the Swedish medical profession returned from their midsummer vacation to attend a subscription dinner given to us in the beautiful building of the Swedish Medical Society. Professor Jakobaeus presided, and many words of goodwill and admiration for America were heard. On Sunday, Professor Key took our surgeons for a yachting excursion over the beautiful waters of the archipelago coast of Stockholm, while the rest of the party sailed to Saltsjöbaden, the picturesque seaside resort. We saw the model physical therapeutic establishment of Dr. Aberg there, and were his guests for dinner. Afterwards several of our members took a hydroplane ride over the beautiful waters of the Archipelago and the Baltic Sea. The four days' visit to Stockholm left unforgettable memories with all of us.

PROFESSOR G. FORSSELL
in yard of *Radiumhemmet*, Stockholm

DENMARK

Two days were spent in the historical capital of Denmark, Copenhagen. The approach by train ferry across the Oresund from Malmo presents the city picturesquely. The enormous bicycle traffic on its streets is unique. The two principal hospitals visited were the magnificent Rigshospitalet (University hospital), a state institute, and the Bispebjerg Hospital of the City of Copenhagen. The former provides for the training of doctors, midwives and nurses. Each of the seven general departments has its own amphitheatres, laboratories, libraries and collections for the use of students, all buildings being connected by a corridor. The total bed capacity is 974. Professor Knud Faber, the internist of repute, was our guide, and presided at a luncheon given by the hospital. Our president, Dr. Fred H. Albee, gave a talk on his work in bone grafting, illustrated by moving pictures, before the Danish Society of Surgeons, in the surgical amphitheatre, which was packed to capacity with an appreciative audience. The Bispebjerg Hospital is a very large modern institution, built in garden pavilion style with underground corridor connection. In both hospitals the entire staff, including attendants, live on the grounds in fine separate buildings and devote their entire energy to the patients and to teaching. A most complete department of physical therapy is attached to each hospital and is used extensively. The per capita cost is, as in all Scandinavian hospitals, complained of as being very high, though the cost to the individual patient is quite low.

The Finsen Institute for light therapy is the unique institute of Copenhagen. From small beginnings in 1895 it has grown to a bed capacity of 220, treating 250 patients daily. Employing concentrated carbon arc light through a water cooled quartz compressor, the results were 59.6 per cent. cures in two thousand cases of lupus between 1899 and 1914. Since the addition of general carbon arc light baths by the present chief, Axel Reyn, the percentage of cures has reached eighty-nine per cent. and also includes various forms of surgical tuberculosis (bones, joints and glands). Local treatment has also been used with good results in nontuberculous skin lesions, chronic eczema, x ray and radium dermatitis. The technic used is very exacting; the average local treatment takes about seventy minutes, the general treatment up to two and one half hours each time. The sight of the big treatment hall in which thirty patients are treated by highly skilled nurses, usually in groups of four, each group from a central lamp, is an impressive one. Dr. Svend Lom-

holt, associate director, gave a very thorough lecture on the principles and technic of treatment. We stood in reverence before the statue of Niels Finsen, who died young from heart disease, and visited his private office, left just as it was when he died in 1905. His original technic and the line of investigations outlined by him are scrupulously observed. His widow joined us at the luncheon given by the Institute.

(To be continued)

News Items.

Buffalo Has New Filtration Plant.—The city of Buffalo has recently completed the construction of a mechanical filter plant for treating its water supply, which comes from Lake Erie. The plant consists of forty filter units each having a capacity of four million gallons a day, thus providing a total capacity of 160,000,000 gallons in twenty-four hours.

Illinois Conference Changes Dates.—The Illinois Conference on Public Welfare has changed the date of its meeting from October 18th-20th to November 14th-16th, because the former dates conflicted with those of the American Prison Congress. The Illinois conference will be held at Mt. Vernon. Its general theme will be Fixing the responsibility for treating human ills.

New Members of Mental Hygiene Committee.—The following new members have recently been appointed to the Committee on Mental Hygiene of the New York State Charities Aid Association: Chellis A. Austin, William A. Chadbourne, Mrs. James Russell Parsons, Dr. Frederick W. Parsons, superintendent of the Buffalo State Hospital; Dr. John R. Ross, superintendent of the Harlem Valley State Hospital; and Dr. Clarence O. Cheney, who has been appointed superintendent of the Hudson River State Hospital.

Rockefeller Institute Appointments.—The Scientific Staff of the Rockefeller institute for Medical Research has announced the following promotions and appointments: Dr. Charles R. Stockard has been elected a member of the Board of Scientific Directors; Dr. John W. Gowen, Prof. Duncan A. MacInnes and Dr. Norman R. Stoll have been appointed associate members; Dr. Eggert Möller has been appointed associate; assistants appointed are: Mr. Lawrence R. Blinks, Dr. Philip G. Cohen, Dr. Walter P. Covell, Dr. John A. V. Davies, Dr. Lewis A. Eldridge, Jr., Dr. Jacob Furth, Dr. Donald M. Hetler, Mr. Thomas P. Hughes, Mr. Alfred G. Jacques, Dr. Lawrence S. Kubie, Dr. Eaton M. MacKay, Dr. Julius Sendroy, Mr. Henry Stevens, Dr. Fred. W. Stewart, Dr. Alphonse Walti, Dr. Rudolf W. Glaser and Dr. Philip D. McMaster have been promoted from the rank of associate to associate members; Dr. Charles A. Doan, Dr. Douglas A. Drury, Dr. James A. Hawkins, Dr. Moses Kuntz, Dr. Clara J. Lynch, Dr. Ida W. Pritchett and Dr. Lars A. Welo have been made associates.

Annual Conference Program Announced.—The Annual Conference of Health Officers and Public Health Nurses, to be held in Buffalo October 12th at the Statler Hotel, will form a part of the annual convention of the American Public Health Association. The following tentative program has been announced: 10 a.m., introductory address by Dr. Matthias Nicoll, Jr., Commissioner of Health of New York State; What New York State Is Doing for Cripples, by Lewis A. Wilson, director of the Division of Vocational and Extension Education of the New York State Department of Education; Progress of the Toxin-Antitoxin Campaign in New York State, by Dr. Edward S. Godfrey, Jr., director of the Division of Communicable Diseases of the New York State Department of Health; 2 p.m., address by Dr. George M. Fisher, president of the New York State Medical Society; Progress of Infant and Maternity Hygiene Work in New York State, by Dr. Elizabeth M. Gardiner, director of the Division of Maternity, Infancy and Child Hygiene of the New York State Department of Health; Control of Nuisances by Local Health Officers, by Charles A. Holmquist, director of the Division of Sanitation of the New York State Department of Health.

New Clinic in Philadelphia.—The Social Service Department of St. Christopher's Hospital for Children in Philadelphia has recently opened a neuropsychiatric clinic for children at that institution, according to the *Mental Hygiene Bulletin.* The clinic functions under the auspices of the hospital's Department of Preventive Medicine. All medical, surgical and laboratory work, except x ray, is carried out within the hospital.

Dusseldorf Exhibit.—Health in many aspects is being featured at the great German health exhibition at Dusseldorf. The Institute for Tropical Hygiene of Hamburg, the Museum for Hygiene of Dresden, the International Red Cross, and the Health Section of the League of Nations are among those exhibiting. One of the features of the exhibition is the *Haus des Aerztes,* the Pavilion of Physicians. The exhibit on housing and settlements stressses fire prevention organizations, watering devices, sanitation, heating and ventilation, and food and clothing. In another section, the leaders of science in Germany, colleges and academies of practical medicine, and several private clinics present the results of their work and investigations. The exhibition covers an area of nearly one hundred acres.

A New Square Club.—The Physicians' Square Club of Greater New York composed of Master Mason physicians, visited Philadelphia on Wednesday, August 18th, in order to initiate the newly organized Physicians' Square Club of Philadelphia. The initiation ceremonies were held at the Hotel Seville, at which about thirty members of the new organization were installed, by the Superior Healer of the Physicians' Square Clubs of America and the Sublime Healer of the New York Physicians' Square Club.

Addresses were delivered by a number of distinguished physicians both from New York and Philadelphia. A collation was held at the Hotel Seville after the ceremonies, at which time the date for the annual convention of Physicians' Square Clubs of America was set for the last week in September, 1926, to be held at Philadelphia, at which time a visit will be made to the Sesquicentennial Fair.

School of Tropical Medicine.—The School for Tropical Medicine established by Columbia University at Porto Rico will be formally opened on September 22nd. Dr. Robert A. Lambert will be director of the new school. Cooperating with it will be the Plague Prevention Laboratory of the Porto Rico Department of Health and the Insular Leper Hospital. Among members of the faculty will be Prof. Donald H. Cook, and Prof. William A. Hoffman, both of Columbia University; and Francesco J. Hernandez, Pedro Gutierrez Igaravidez, Isaac Gonzalez Martinez and Arturo Torregroas. Prof. Earle B. Phelps, of Columbia, will be visiting professor in the fall of 1926. Officers of administration in addition to Dr. Lambert will be Thomas E. Benner, Chancellor of the University of Porto Rico, and President Nicholas Murray Butler of Columbia University.

Civil Service Examinations.—The following openings are announced by the U. S. Civil Service Commission:

Social worker (psychiatric): applications must be on file in Washington, D. C., not later than September 21st; the examination is to fill vacancies in the Veterans' Bureau, and in positions requiring similar qualifications throughout the United States. The duties are to investigate history and environmental conditions of patients; to analyze and submit data to the physician to aid him in arriving at a definite diagnosis and in outlining a course of treatment; to consider, report upon, and treat the social environment to which a convalescent patient may go or be expected to go. Competitors will be rated on their education, training, and experience; and a thesis or publications to be submitted with the application.

Medical officers: Applications will be rated as received at Washington until December 30th; the examinations are to fill vacancies in the Indian Service, Public Health Service, Coast and Geodetic Survey, Panama Canal Service, Veterans' Bureau, and other branches. The examinations are of five grades: junior medical officer, assistant medical officer, associate medical officer, medical officer, and senior medical officer. Eligibles are needed who are qualified in general medicine and surgery. There is special need for eligibles qualified in the various specialties. Practically any specialty may be named by the applicant. Competitors will not be required to report for examination at any place, but will be rated on their education, training and experience.

Personal.—Dr. James Garfield Dwyer of New York attended the recent annual meeting of the American Laryngological, Rhinological and Otological Society held in Montreal, where he discussed the present conception of the etiology of focal infections.

Dr. Aaron Leifer has been appointed instructor in medicine at University and Bellevue Medical College, New York City.

Dr. Marks S. Shaine has been appointed instructor in Medicine in the Department of Gastroenterology at Columbia University. He has also been made consulting gastroenterologist to the Rockaway Beach Hospital.

Dr. Joseph J. Eller has returned to New York after a study of dermatological institutions in Europe.

Dr. Robert Bierich, director of the Cancer Research Institute of Hamburg, is expected to visit this country to attend the conference on cancer research to be held at Lake Mohonk, September 20th-24th. Dr. Bierich is available for lectures on cytochrome and carbohydrate metabolism in cancer.

Dr. George D. Wolf is in Europe studying the otolaryngological clinics of Germany and Austria.

Dr. Joshua E. Sweet, who for the past twenty years has occupied the chair of surgical research at the University of Pennsylvania, has been appointed head of the same department at Cornell University Medical School.

Dr. Howard Fox has been made chairman of the recently established Section on Dermatology and Syphilology of the Medical Society of the State of New York.

Dr. Albert B. Hastings, formerly associate in the Department of the Hospital of the Rockefeller Institute, has accepted an appointment of professor of physiological chemistry at the University of Chicago.

Dr. Kessiakoff and Dr. Golosmanoff of Bulgaria and Dr. Ciuca and Dr. Popp of Rumania were recent visitors at the New York State Department of Health, Albany.

Dr. Leroy W. Hubbard, for nine years orthopedic surgeon of the New York State Department of Health, has been granted four months' leave of absence to direct experimental work in the after treatment of poliomyelitis cases by exercise in warm water to be carried on at Warm Springs, Georgia.

Dr. David I. Hitchcock, formerly associate in the Division of General Physiology at the Rockefeller Institute, has been appointed associate professor of physiology and biochemistry at Bryn Mawr College.

Jane C. Allen, instructor at Teachers College, Columbia University, has resigned her position to become director of the National Organization for Public Healtth Nursing. Miss Allen received her professional education at St. Luke's Hospital, Chicago, and has done graduate study at the University of Chicago, the University of California, and Teachers' College.

Dr. Pedro N. Ortiz, Commissioner of Health of Porto Rico, delivered addresses recently in New York City, Philadelphia and Boston.

Miss Janet Grame Travell received the John Metcalfe Polk Memorial Prize of $300 as winner of the highest honors of the sixty-three graduates of the Cornell Medical School. She is the second woman to receive the prize.

The honorary degree of LL.D. was conferred upon Dr. William H. Rankin, of Brooklyn, by Queens University, Kingston, Ontario, at its annual convocation. He was graduated from the university nearly forty years ago.

Sister Mary Veronica Ryan, superior and superintendent of the Mercy Hospital, Chicago, was recently given the degree of Doctor of Laws by Loyola University in recognition of her services to the technique of surgery in operating rooms.

Dr. George A. Green of Mechanicsville has been elected Department Commander of the Veterans of Foreign Wars of New York State. Dr. Green was overseas with the Fifth Division. He has served as Department Surgeon and Deputy Inspector and last year was Senior Vice Commander.

Dr. Arthur Landsman was elected president of the medical board of the Jewish Memorial Hospital at the recent annual meeting of the board, and other officers were elected as follows: Dr. Samuel Weiss, first vice-president; Dr. Edward Bleier, second vice-president, and Dr. Louis Neuwelt, secretary.

Gifts and Bequests.—The New York Skin and Cancer Hospital received $300,000 as a contingent bequest from the estate of the late Ralph Holden.

The Memorial Home for the Blind, Worcester, and the Perkins Institution for the Blind, Watertown, Massachusetts, each received $5,000; the Home for Aged Women, the Home for Aged Men, Associated Charities, Worcester Tuberculosis Relief Association, and the Worcester Society for District Nursing, each received $2,000 by the will of the late David Hale Fanning, of Worcester.

One thousand dollars was bequeathed to the Brooklyn Home for Consumptives by the late Grace Newman.

The will of the late Mrs. Mary de Silver Lord provides $2,500 for St. John Guild's Seaside Hospital, New York, and $10,000 for St. Bartholomew's Hospital, New York.

Frederick Brown has donated one hundred thousand dollars to the Jewish Hospital of Brooklyn.

Strasbourg Courses in Cancer and Tuberculosis.—A course in cancer study and treatment is offered by the Faculty of Medicine of Strasbourg to extend from October 18th to November 26th. Dr. Gunsett, director of the anticancer centre of Strasbourg, will be in charge of the course, assisted by Professor Borrel, Professor Canuyt, Professor Leriche, Professor Masson, Professor Pautrier, Professor Schickelé, Professor Stolz, Professor Weil and Professor Vles, all of the Faculty of Medicine of Strasbourg; Professor Coulon of Lausanne, Mme. S. Laborde, director of radio and Curietherapy at the Cancer Centre, Paris; Professor Mallet and Professor Roussy of Paris, and Professor Neumann and Professor Coryn of Brussels. The Strasbourg Faculty of Medicine, in cooperation with the Association of Alsace and Lorraine against Tuberculosis, offers also a course in the study and treatment of pulmonary tuberculosis and other diseases of the respiratory organs, to extend from October 8th-23rd. Dr. G. Canuyt and Dr. E. Vaucher will be in charge of the course, assisted by Professor Cade of Lyons, Dr. Pasteur Vallery-Radot and Dr. Weill-Halle, of Paris; Professors Léon Blum, Leriche, Merklen, Rohmer, Boez, Gery, Gunsett, Belin, Woringer, Ohlmann, Schaaf, Froelich, Kaufman and Zillhardt, all of Strasbourg; Dr. Brion of Robertsau and Dr. Fath of Altenberg.

Letters to the Editor.

A EUROPEAN STUDY TOUR

New York, *August 25, 1926.*

To the Editor:

The Travel Study Club of American Physicians has just completed its second study trip to some of the medical centres of Scandinavia and western Europe, visiting Oslo (Christiania), Stockholm, Copenhagen, Hamburg, Dusseldorf, Cologne, Neuenahr, Wiesbaden, Heidelberg, Baden-Baden, Berne, Leysin, Paris and London. It is our pleasant duty to state that authorities, medical and municipal, in all of the places visited, arranged for inspection of medical and scientific institutes and for special clinics in a most thorough manner, and that leading men of the profession have shown a spirit of welcome and an amount of hospitality that we never can hope to be able to return adequately. While in comparison we can be justly proud of the recent progress in American medical teaching and research work and the interest displayed towards it abroad, there is a great deal in clinical teaching and laboratory work in some of the European centres that is unique and well worth studying. Records of our study trip are being deposited with the Committee on Medical Education of the New York Academy of Medicine, and by writing there or to the undersigned are available to any physician in the United States.

Richard Kovacs, M.D., *Secretary.*

Book Reviews

DIAGNOSIS

Differential Diagnosis. By Richard Cabot, M.D., Professor of Medicine and Professor of Social Ethics at Harvard University. Vol. II, Third Edition. Philadelphia and London: W. B. Saunders Co., 1926.

In this edition, as stated in the preface, while the cases are unchanged, the introductory discussions have been modified and enlarged.

The cases are grouped under the following headings—abdominal and other tumors, vertigo, diarrhea, dyspepsia, hematemesis, glands, melena, swelling of the face, hemoptysis, edema of the legs, frequent micturition and polyuria, fainting, hoarseness, pallor, swelling of the arm, delirium, palpitation and arrhythmia, tremor, and finally ascites and abdominal enlargement.

A feature is the listing and graphic representation in black ink of the cause of disturbances, while titles of cases, such as passive congestion of the liver and appendicitis that are "too many and too vaguely enumerable for graphic representation" are listed in red ink. In swollen face, for instance, one generally overlooks trichiniasis. It is the differentials like this that increase the value of the book.

Where necessary there are fever charts and frequent diagrams of surface markings to indicate physical signs.

The cases are presented in a concise, interesting manner, with the discussion and outcome included. In the section on tumors the echinococcus fixation test is suggested. Cabot thinks mucous colitis is a form of neurosis. (Another doctor would remark that most women over thirty-four have it.) In the chapter on dyspepsia attention is called to the fact that there are only two truly gastric causes of indigestion, namely cancer and ulcer.

The book is for those possessing a clear perspective and a rapid power of valuation. It is essentially a reference book. After perusal one realizes that it is best to think several times whether for a given case it is absolutely necessary to use surgery. The unexpected so often happens in diagnosis. In short, the volume is a masterly product, the result of long observance of cases quite baffling.

Medical Diagnosis. For the student and practitioner. By Charles Lyman Greene, M.D. Sixth Edition, revised and enlarged with 14 colored plates and 709 other illustrations. Philadelphia: P. Blakiston's Son and Co., 1926.

This volume, revised, shows the effort to increase the practical value of a most commendable book. The 1468 pages including the 159 pages of general and symptom index fused are none too many. The print is large and the margins deep enough for added comments.

Twenty pages delineate the substance which considers fundamental principles, and special problems, case taking, the blood, glands, kidneys and so on through infectious diseases, parasites, the intoxications, malingering, conditions simulating death, and a brief summary of the symptoms and treatment of acute poisoning. The marginal notations for almost every paragraph, marking the content of thought, are a great relief for quick references and as an aid to memory.

With the voluminous laboratory tests which are most worthwhile, the abundant x ray photographs, colored illustrations of retina disturbances, drawings of parasites, and pictures of typical cases, fever and other charts, there seems as if nothing had been omitted necessary for differential diagnoses.

Nowhere in a book of this sort has there been such a clear, lengthy exposition of cardiac disturbances. Approximately one fourth of the book is devoted to the subject. Electrocardiograph tracings, diagrams, x ray pictures including twenty-four röntgenograms of the behavior of the heart outline under rational treatment elevate Greene's work to the peerless class.

HAY FEVER

Hay-Fever and Asthma. A Practical Handbook for Hay Fever and Asthma Patients. By Ray M. Balyeat, A.M., M.D., Instructor in Medicine in the University of Oklahoma Medical School. With twenty-seven illustrations. Philadelphia: F. A. Davis Company, 1926. Pp. 198.

This little manual is the result of the need felt to supply a book that will explain the chief causes of asthma and hay fever and outline the routine management of patients suffering with these diseases in terms that are intelligible to the average layman. The reader is acquainted with the modern methods used in determining the causes of these conditions. As most of the cases of hay fever and many cases of asthma are traceable to the dissemination of pollens of plants, their dates of pollination are given. Another prolific cause, domestic animals, fowls and dusts, are also discussed. Finally, the methods of testing patients and the procedures employed in the preparation of therapeutic remedies are described in great detail.

Handbooks of this type serve a valuable purpose in that they penetrate the socalled mysteries of medicine and teach patients suffering from these diseases how to protect themselves against their surroundings.

UROLOGY

A Text Book of Urology. By Oswald Swinney Lowsley, A.B., M.D., F.A.C.S., and Thomas Joseph Kirwin, Ph.C., B.S., M.A., M.D. Illustrated with 233 Engravings and 13 Plates. Philadelphia and New York: Lea and Febiger, 1926.

The authors have produced an excellent volume on urology, based on eighteen years of intensive study devoted to laboratory research and clinical experience. A vast amount of useful matter has been gathered within the compass of a single volume of less than seven hundred pages. In a well written foreword, the authors emphasize the fact that for the practice of urology, whether as a specialty or merely in the course of more general practice, familiarity with many diagnostic methods and high technical skill in the use of mechanical apparatus, is a major essential.

Rather more than usual space is devoted to a consideration of the glass tests, a feature of great importance in the opinion of the present reviewer. It is difficult to understand why so many authors of urological works devote so little attention to these

highly important tests. The present authors are to be complimented on their fairly complete presentation of these tests.

In a work of such general excellence it is difficult to select anything in particular for praise. The subject is thoroughly covered and the style of presentation all that could be asked for. It was to be expected that certain phases of the subject would be emphasized, among these being the use of regional anesthesia for operative work, the authors having devoted much time and study to this subject. Here and there unimportant errors may be observed, but these can be corrected in future editions.

The authors and publishers are to be congratulated on the publication of this work. They have added another to the list of splendid works by American urologists.

MEDICAL PRACTICE

Taylor's Practice of Medicine. By E. P. Poulton, M.D. Oxon. Thirteenth Edition. Philadelphia: P. Blakiston's Son and Co., 1926.

The author calls attention to the new articles included, such as pluriglandular syndromes, melioidosis, tularæmia, chronic manganese poisoning, lipiodol injections and peroneal muscular atrophy. The three features of the book, enumerated, are the list of references and authors at the end of each section, the x ray pictures and the colored plates.

Clearly explanatory diagrams abound, such as photographs of sections of the spinal cord in various diseases. The large number of x ray pictures give students the visualizations they need for correlation of ideas. Fever charts, electrocardiogram tracings, several colored illustrations including a complete pictorial symposium, with Jenner's and Leishman's stains on normal and abnormal blood cells, enable rapid assimilation.

Brackets containing percentages follow data under discussion. The subject of treatment naturally produces a variation of opinion. For example, on page 874, bromides are given preference over luminal: in this country the reverse is favored, and not in such large doses as mentioned. However, the student's observation, textbook and clinician's instruction, indicate the elasticity permitted.

As a superior text and reference book for students this edition strongly commends itself.

RADIOTHERAPY

Ergebnisse der medizinischen Strahlenforschung (Röntgendiagnostik, Röntgen-, Radium-und Lichttherapie). Herausgegeben von H. Holfelder, Frankfurt a.M., H. Holthusen, Hamburg, O. Jüngling, Tübingen, H. Martius. Bonn a Rh. Band II. Mit 520 teils farbigen Abbildungen im Text und auf 3 photographischen Tafeln. Leipzig: Verlag von Georg Thieme, 1926. Pp. 594.

Like the first volume, this the second volume deals with the physical, biological, microscopical, anatomical, physiological and therapeutic aspects of irradiation. Heretofore these subjects were scattered throughout the literature of the world, but now they are available in one work. The various subjects are treated by experts in their various fields. Detailed discussion is impossible in a short review, but we cannot give too much praise to this beautiful and complete work.

O. Jüngling describes the diagnostic value of ventriculography and encephalography in cerebral diseases, with special consideration of brain tumors. H. Peiper discusses the diagnostic value of myelography in spinal cord diseases. The röntgenogram of interlobar pleuritis and its differential diagnosis is the work of F. Fleischner. The article on the direct röntgen symptoms of duodenal ulcer and its clinical significance by H. H. Berg is very valuable. The article by C. Kroetz on the influence of short wave rays upon the acid base balance in the body, especially on the reaction of the blood, deals with material concerning which little is as yet known. F. Klewitz contributes the article on the irradiation treatment of bronchial asthma. F. C. Geller writes about the results of experimental irradiation of the ovary. A very excellent contribution is made by K. Scheele on endovesical electrocoagulation. The röntgen and radium treatment of carcinoma of the tongue is the work of E. Schempp.

The illustrations are very numerous and leave nothing to be desired in beauty and instruction. Each monograph is followed by a bibliography which is very complete and up to date and includes the literature of the world. No radiologist should be without this valuable work.

METABOLIC AND DIGESTIVE DISTURBANCES

Sammlung zwangloser abhandlungen aus dem Gebiete der Verdauungs-und Stoffwechsel-Krankheiten. Mit Rücksicht auf allgemein-ärztliche Interessen, herausgegeben von Professor Dr. H. Strauss in Berlin. Halle a.S.: Carl Marhold Verlagsbuchhandlung, 1925.

I. Band, Heft 4. Indikationen und Technik der Entfettungskuren. Von Prof. Dr. Paul Friedrich Richter, Berlin, dirig. Arzt am Krankenhaus Friedrichshain. Zweite vermehrte und verbesserte Auflage.

III. Band, Heft 7. Die diagnostische und prognostische Bedeutung der Harnsedimente nach neueren Anschauungen. Von Dr. med. et phil. C. Posner, ao. Prof. an der Universität Berlin, Geh. Medizinalrat. Zweite neubearbeitete Auflage.

IX. Band, Heft 2. Die Enterie (enterogene Neurasthenie), ihr Wesen und ihre Behandlung. Von Dr. Paul Cohnheim, Berlin, Facharzt für Magen-u. Darmkrankheiten.

After discussing the reasons for the present day demand for the reduction of obesity, Richter divides the indications therefore into general, circulatory diseases, metabolic diseases, nervous diseases, diseases of the locomotor apparatus, and pulmonary diseases. The various types of therapeutic technic, such as dietotherapy, water drinking courses, massage and active movements, hydrotherapy and drug therapy are discussed in detail. Much attention is given to thyroid gland therapy.

After some introductory remarks upon the general value of microscopical examination of the urine and the reliability of the usual laboratory reports, Posner divides his material into two parts: the metabolic products found in the urinary sediment, such as, 1, uric acid and its salts, the urine in gout and uric acid diathesis; sodium urate and ammonium urate; 2, the phosphoric acid salts and earths, phosphaturia and calcariuria; 3, the oxalic acid earths, oxaluria, atypical crystals and their relationship to calculus formation; 4, other earths, calcium carbonate, calcium sulphate and magnesium phosphate; 5, cystin; and 6, ammoniacal combinations, ammonium magnesium phosphate.

The second part of the monograph is concerned with the products of local disturbances: 1, epithelial cells of the various parts of the urinary tract, metaplasia, and fatty and lipoid cells; 2, leucocytes, normal and pathological cells, staining, and local diagnosis by pyuria; 3, erythrocytes, localization by hematuria, and various forms of urinary bleeding; 4, nubecula, cylindroids, casts and their significance; 5, microorganisms, bacteriuria, infection, the various forms of pathogenic bacteria, amebæ, bilharzia and echinococcus; 6, admixtures from the sexual organs and accessory glands, such as the prostate, seminal vesicles and urinary filaments.

This is a comprehensive and valuable but concise résumé of the subject. He mentions the use of dark field microscopy in the study of the cellular elements, of which the English literature contains little or nothing.

Paul Cohnheim discusses enterogenous neurasthenia, its nature and its treatment. The term "enteritis" includes all those cases of a chronically diseased intestine originating with local and general reflex symptoms, essentially of a vasomotor nature. They are never a primary disease condition, but always secondary to intestinal involvement. The symptomatology includes local symptoms, symptoms in other organs, disturbances in the general condition and enterogenic psychopathies. The matter of differential diagnosis is important. The treatment includes limitation of gas formation by dietary measures, the inhibition and elimination of pathological products of fermentation, treatment of the colitis and improvement of the nervous condition.

CLINICS

The Medical Clinics of North America. Issued serially, one number every other month. Volume X, Number 1, Philadelphia Number, July, 1926. With twenty-four illustrations. Philadelphia and London: W. B. Saunders Company. Pp. 260.

The Philadelphia Number of the *Medical Clinics* features a study of bronchoscopy in disease, by Gabriel Tucker, of the Chevalier Jackson Bronchoscopic Clinic, in which a series of most unusual cases is reported. A total of twenty-one clinics is presented, the subjects covering a wide field. Strecker presents an interesting clinic on paresis *sine* syphilis, and Mohler discusses at length the significance of precordial pain. Carcinoma of the bronchus is presented in a clinic by Thomas McCrae, and the treatment of polycythemia vera with phenylhydrazin, by Simon Leopold. Twenty-three contributors make up this interesting number.

The Surgical Clinics of North America. Issued serially, one number every other month. Volume VI, Number III. Lahey Clinic Number, June, 1926. With fifty-four illustrations. Philadelphia and London: W. B. Saunders Company. Pp. 214.

Twenty-one clinics are contributed by eight members of the Lahey Clinic staff, most of the subjects being allied to the subject of goitre. Lahey emphasizes the modification of his method of treatment, which has resulted from the introduction of iodine. The management of cases of primary hyperthyroidism or exophthalmic goitre today in the clinic consists of preoperative rest and Lugol's solution, until it is evident that the most marked degree of gain has been made, as evidenced by improvement in symptoms and a drop in basal metabolic rate. Usually eight to twelve days are required for this improvement to become manifest, though there is no regularly fixed time. Of his cases thus treated, 92.8 per cent. have shown a definite drop in basal metabolic rate, while the remainder either have shown no drop or have shown an increase in basal metabolic rate. Another important result of this treatment is that there has been a markedly diminished number of multiple stage operations.

Burton Hamilton contributes an instructive clinic on the chronic cardiac as a surgical risk, and Robert Mason offers a most useful clinic in which he discusses some physiological aspects of postoperative treatment. The volume maintains the usual high standard of the *Surgical Clinics.*

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, with the Collaboration of Distinguished Medical Authors. Volume 1, Thirty-fifth Series, 1925. Philadelphia and New York: J. B. Lippincott Co., 1925.

This volume consists of articles presented by twenty-three contributors. Dr. Lewellys F. Barker, of Baltimore, leads with two excellent clinics. The articles are arranged under group titles, such as diagnosis and treatment, mental disturbances, surgery, toxicology and the progress of medicine by the editor. These articles are well written and presented in an interesting manner.

It is to be regretted, however, that the value of this number should be marred by two atrocious examples of rank plagiarism. Dr. Thomas M. Dorsey and Dr. Rudolph Monaco, both of Louisville, Ky., present a long article entitled Some of the Urological Problems Most Frequently Encountered in Daily Practice. This article has been plagiarized bodily, practically word for word and line for line, from an article by Dr. A. L. Wolbarst, of New York, which appeared in 1922, in the *Virginia Medical Monthly.* Another article in the same issue, under the authorship of the same Dr. Dorsey in association with Dr. F. C. Bohannan, entitled Pyuria, with Special Reference to Causation, likewise is a rank plagiarism of another article written by Dr. Wolbarst and published in the *Medical Record,* of February 12, 1922.

The editor and publishers have made a public apology for having accepted and published this plagiarized material, in the December, 1925, issue of *International Clinics.*

AYER LABORATORY BULLETIN

Bulletin of the Ayer Clinical Laboratory of the Pennsylvania Hospital. No. 9. Issued October, 1925. Philadelphia, Pa.

This issue contains seven articles, the last three dealing with postmortem blood chemical determinations, a micromethod for determining blood sugar, and a note on the preservation of hydrogen ion standards. A. E. Billings and J. R. Paul have written a most interesting and comprehensive paper on tumors of lateral aberrant thyroids. They present a résumé of cases published since 1857, totalling thirty-four cases, to which they add their own case of papillary adenocarcinoma of a lateral aberrant thyroid gland, with illustrations of the microscopic picture. The other papers deal with acute massive and partial collapse of the lungs, and pneumococcus infections.

Medicoliterary Notes.

Electrons, supposed to be the smallest things in the world, are now supplanted by even smaller particles surrounding the parts of which atoms are built up, according to the statement made in a recent lecture before the Institute of Electrical Engineers, by Sir Joseph Thomson, a leading British physicist.

* * *

In contrast to the accepted theory that hard times produce an increase in disease and a higher death rate, Dr. Huntington of Yale has been quoted as stating his belief, that, while there is more sickness and mortality during periods of business depression, hard times are always preceded by a lowering of the general health and an increasing death rate; so the panicky state of mind, according to his theory, responsible for creating a financial crisis, is in reality due to the weakening effects of ill health.

* * *

Sir Humphrey Rolleston, of the Medical Faculty of Cambridge, in a recent lecture before the Harrowgate Medical Society, gave a summary of the existing evidence pro and con tobacco using. Psychological tests show that smoking lowers mental efficiency from ten to twenty-three per cent., and it is suggested that premature senility is induced in heavy smokers by the sedative action of nicotine on the nervous system; it may also produce dilatation of the stomach. But those who chew or dip snuff need not worry, for these practices are "attended by so little absorption of nicotine as to be comparatively free from untoward symptoms."

The book publishers of America have formed a national committee to aid in the work of erecting a national press shrine to be placed in the Cathedral of St. John the Divine in New York. The shrine will take the form of a chapel opening from the side of the great nave or central aisle, and will rise 115 feet from the floor to the roof. Stained glass windows will record some of the activities of the press and its part in the progress of civilization, and somewhere in the scheme of decoration an appropriate place may be found for the names of those outstanding figures who have added lustre to the profession. The cost of erecting and equipping the chapel will be from $150,000 to $225,000. —*N. Y. Times.*

Announcement has been made through the press of a discovery, made by Dr. A. V. Blom, of Switzerland, that may lead to extremely important developments. Dr. Blom is reported to have invented a new lead paint which affords complete and permanent protection of iron from rust. Experiments made with iron objects painted with this new preparation do not show any signs of rust after prolonged exposure or even after having been heated in steam.

The National German Society for the Protection of Children has recently made public a report on employment of children in Germany. They attribute the increased employment of children on farms to poverty, labor shortage, the demand of adults for higher pay, and the influx of school graduates into industry. The report states that the average age at which these children begin to work is ten years, but that some have been found working when only four or five years of age. Working hours vary in length from two to twelve hours—two to five in winter and two to twelve during the rest of the year.

* * *

Announcement has recently been made of the discovery of a local anesthetic declared to be superior to cocaine. It has been developed through three years of experimentation by Prof. S. M. McIlvain, of the University of Wisconsin, with the assistance of a research worker, Ralph Jones. The drug consists of piperidine derivatives and is closely related in structure to cocaine, but has two and a half times the duration of anesthesia and one tenth the toxicity of the latter. Unlike novocaine, the piperidine derivatives need not be injected, but will produce surface anesthesia.

* * *

Report comes from France of the establishment in French country houses of what is known as an "American bar." These have been installed in the smoking rooms, libraries, etc., of many châteaux, with a professional white coated bar keeper behind the counter, and with high stools for the "customers." All of these are likely to be occupied at "cocktail hour," which is supposed to be another American custom.

* * *

A skin test for susceptibility to infantile paralysis has been discovered, according to reports. The discoverer is Dr. Edward C. Rosenow of the Division of Experimental Bacteriology of the Mayo Foundation. Redness of the skin at the end of eighteen to twenty-four hours at the point of injection is thought to indicate susceptibility. A serum prepared from the blood of horses immunized with the streptococcus prevents toxic reaction.

* * *

During the latter part of the school year in June, Needham, Mass., opened a "whooping cough school." So many pupils had to be absent from the public schools on account of having the disease, that the Superintendent of Schools obtained permission to open a school for whooping cough patients who had recovered sufficiently and thus prevent their failure in promotion. One group attended in the morning in a portable building adjoining the hospital, and another lot of children came in the afternoon.

The third part of Romain Rolland's new novel, *The Soul Enchanted,* of which *Annette and Sylvie,* and *Summer* have already appeared, will be published in this country in January by Henry Holt & Company under the title *Mother and Son.* It will consist of two volumes.

* * *

The U. S. Department of Agriculture has recently issued two important bulletins, one a warning against fraudulent radioactive waters and drugs, and the other the revision of the standards for milk products.

* * *

The inventiveness of school children and the renowned alibis of office boys during the baseball season must pale before the latest tale of a chorus girl's creative imagination. The stage manager of a current Shubert production the other day received a note from one of the chorus ladies reading: "Please excuse me for not attending today's matinée as I am sick in bed with a bad attack of typhoid fever. However, I will positively be around for tonight's performance."—*The New Yorker.*

* * *

That cleanliness is quite costly is shown by estimates of just how much it costs to keep clean, published in a recent issue of the *Labor Woman.* The estimate of the average cost of cleanliness per person per month is given as at least $10.95. Because the individual items are insignificant in themselves, it is difficult to realize that the sum total can be so high. An incomplete list of cleansing agents used in the average family might include the following: soap powder, floor polish, toilet soap, bath salts, laundry soap, shoe polish, shampoo powder, tooth paste, etc., to say nothing of the paraphernalia for keeping clean, such as scrubbing brushes, pans, dust cloths, and other items.

* * *

Floyd W. Parsons, economist and fuel expert, has recently been quoted as stating that in the near future a gas fired absorption refrigerating unit, by means of which a house may be cooled in summer and heated in winter, is a possible development. Heat absorbed by the plant would be pumped into the rooms during cold weather, and in warm weather, cold air produced by the refrigerating unit would be piped through the same pipes. The refrigerating capacity of the apparatus would be approximately one fourth of its heating capacity. A unit that could keep a house at 70° with an outside temperature of 10° below zero, could also, he believes, keep the house at 70° with an outside temperature of 90°.

* * *

Miss Sibyl Creed, the author of *The Shot,* a novel with a psychological outlook and which was reviewed in this journal at its time of publication some two years ago, died in Twickenham near London on August 10th. Miss Creed wrote several books and children's tales, but as she wrote them under different names, her own name is not so well known as it deserves to be. She did not pander to the popular taste. She was an artist in words and phrasing and held to her high ideals. Personally Miss Creed was most retiring and unassuming, well versed in French and English literature and possessed of keen powers of criticism.

Abstracts from Current Literature

ENDOCRINOLOGY

Hyperthyroidism Treated by X Rays.—A. E. Barclay and F. M. Fellows (*Lancet,* March 20, 1926) after studying a consecutive and unselected series of three hundred private cases, come to the conclusion that x ray treatment offers a means of restoring to a useful and moderately active life between sixty and seventy per cent. of patients incapacitated by hyperthyroidism. A further twenty or thirty per cent. will be greatly benefited in health. Cases of the somewhat rare condition of acute toxic goitre seldom come under x ray treatment owing to transport difficulties. They are usually satisfactorily treated by radium. Under both radium and x ray treatment a fulminating type of acute hyperthyroidism has been noted, and has invariably been fatal. Two out of three deaths from hyperthyroidism in this series were of this type, the patient having made satisfactory progress up to a point, and suddenly developing acute symptoms and dying within a few days. The method though slow, is, in competent hands, preeminently safe. The results are permanent, and, so far as can be judged, at least as good as those of surgery. Collaboration, not rivalry, between physician and radiologist is the ideal to be aimed at, for each can do much for the patient afflicted with this disease.

Diabetes as Sequela to Acute Pancreatitis.—Of several hundred cases of diabetes observed by J. P. S. Dunn, S. Vatcher and A. S. Woodwark (*Lancet,* March 20, 1926) two only have been directly attributable to a previous acute infection. There was evidence of the presence of gallstones in both of these cases. The authors draw attention to the significant fact that recent radiograms, taken in the manner advocated by Carman, viz., following (oral) administration of sodium tetrabromphenolphthalein, have given reason to suspect the presence of gallstones in both of the cases reported. Pancreatitis, acute and chronic, being most commonly secondary to infective processes elsewhere, in view of a tendency—more pronounced since the advent of insulin—to find the etiological basis of the individual case of diabetes in a pathological condition confined to the pancreas, the importance of an x ray examination of the entire gastrointestinal tract in every suspected case cannot be too strongly emphasized, both from the point of view of exact diagnosis and from that of treatment.

Simple Goitre.—James Berry (*Lancet,* February 6, 1926) emphasizes the following points in regard to the causation of goitre:

1. Simple endemic goitre is not a hypertrophy but essentially a degeneration of the thyroid gland. The gland is not overactive, but underactive.

2. Whatever may be the connection between iodine and the thyroid gland, there is no reason to believe that a lack of iodine has anything to do with the causation of endemic goitre, as found in the human subject.

3. It is quite certain that, at least in the majority of caases, the disease is produced through the agency of drinking water.

4. There is much evidence that practically all waters which produce goitre contain frequently, although not necessarily at all times and seasons, mineral matter in suspension, usually in an extremely fine state of subdivision.

5. There is also a good deal of evidence that this mineral matter is generally of a calcareous nature.

6. Organic mater in suspension, although capable apparently of causing a hyperplasia of the gland, at least in animals, has not been proved to be the cause of endemic goitre as seen in man.

Iodine Treatment in Hyperthyroidism.—F. Merke (*Schweizerische medizinische Wochenschrift,* January 28, 1926) states that iodine in the form of Lugol's solution in the majority of cases of hyperthyroidism acts surprisingly well in the beginning upon the nervous and gastrointestinal symptoms, as well as upon the pulse and the basal metabolism. This initial remission from iodine seems to be dependent upon the dose of the iodine only to a slight extent. Its maximum effect appears about eight days after the administration of iodine, but this favorable effect is only transient and changes into a marked aggravation after the administration of iodine has been discontinued. A short intensive course of iodine is a valuable adjunct remedy in the surgical treatment of hyperthyroidism; during the iodine remission the danger of the operation is diminished and the plan of the operation may be shortened. If a patient with hyperthyroidism has been given iodine, the amount of thyroid gland tissue should be reduced in amount within a short time; further remission may not be possible. The greater the amount of glandular tissue that remains, the more marked are recurring symptoms of exophthalmic goitre on the cessation of the iodine treatment. There are also rare cases of hyperthyroidism in which the favorable initial effect of the iodine is not observed or it may even act injuriously.

Iodine is and remains, therefore, a two edged sword for the conservative treatment of hyperthyroidism. Attempts at conservative iodine treatment should be made only under careful control, as the pulse and body weight do not give sufficient information as regards the course of the disease.

. Reaction of the Thymus After Fractures.—Study of the thymus gland during the period of healing after experimental fracture leads J. Goldner to conclude (*Archiv für Mikroskopische Anatomie,* 1925), that the several varieties of thymic cells display a true cytogenic unity in spite of their morphological diversity. All are capable of being transformed into Hassall bodies. The course of events following fracture exhibits this transformation more clearly than fasting, röntgenization of the thymus, or injection of adrenalin. The small cortical cells, despite their resemblance to lymphocytes, are distinct from them—thymocytes in fact. It seems not unlikely that under certain physiological and pathological conditions the Hassall bodies may be transformed back again into thymocytes. During the fracture period the thymus undergoes unmistakable changes. Its reaction is characterized by a rapid and complete evolution of thymic cells, by a concomitant modification of all the involutional forms, by the appearance of "meeting centres" in the vicinity of the bloodvessels. Not only the Hassall bodies, but all the cells of the gland take part in its endocrine function. The cytological picture varies at different stages of fracture consolidation. At first the evolution of thymocytes is greatly quickened, but becomes slower after the period of periosteal renewal is over. At this time, on the contrary, the formation of the other cells increases. After the fracture has healed the thymus resumes its normal aspect and structure.

Experimental Studies of Infundibular Diabetes Insipidus and Tuberian Diabetes Mellitus.—During the past twelve years Camus and Roussy have established the experimental production of transient polyuria and of permanent diabetes insipidus by lesion of the infundibulotuberian region. They find that the pituitary gland takes no part in producing the phenomenon, and that the substance of the tuber always undergoes a change when the urinary output is increased. Polyuria does not result through nervous activity alone: the infundibulotuberian lesion causes secretory changes which affect the renal secretion. J. Gournay and A. LeGrand find (*Annales de Médecine.,* December, 1925, page 424) that certain lesions of the tuber cinereum cause a glycosuria differing from that of nervous character. It is delayed and protracted. It is specific in nature, being produced only by lesions strictly confined to the paraventricular nucleus. The mechanism of its action remains as yet undetermined.

Action of Pituitary Extract Administered by the Alimentary Canal.—H. H. Knaus (*British Medical Journal,* February 6, 1926) finds that when pituitary extract is administered at any part of the alimentary canal—mouth, stomach, small intestine, rectum—pressor action is never observed. When it is introduced into the stomach or small intestine it exerts no influence on uterine muscle. When it is administered by mouth, after a latent period of about eight minutes it exerts a marked action on the uterus, increasing both the tone and automatic movements. The oxytocic substance is therefore absorbed. The rectum absorbs the oxytocic substance also, although the absorption is probably not so complete.

Fatal Diabetes in a Goitrous Patient Treated with Small Doses of Iodine and with Thyroid Extract.—C. J. Parhon and J. Nitzulesco detail (*Revue Française d'Endocrinologie,* June, 1926, vol. 4, page 189) the history of this case and quote many authors respecting the connection of diabetes with thyroid disturbance. They find evidence of a close relation betwene the thyroid gland and carbohydrate metabolism. Certain cases of goitre, they consider, show a predisposition to diabetes, and the latter disease is especially likely to supervene when treatment with iodine, with thyroid preparations, or by radiotherapy has caused hyperthyrrhemia. They admonish that a careful survey of the thyroid function should never fail to be made in diabetes and its intensity reduced, if necessary. It should also be remembered that insulin may precipitate a hypoglycemic condition of fatal tendency when the liver does not contain a reserve of glucose; and by Sänger and Elsie Hun the glycogenic reserve of the liver has been found reduced in adenomatous goitre.

Multiple Developmental Irregularities and the Endocrine Glands.—Schereschewsky studied (*Revue Française d'Endocrinologie,* June, 1926, vol. 4, page 181) a girl of twenty years prematurely born, very feeble throughout childhood, diminutive in stature, with luxuriant scalp hair but none at axillæ or pubis, suffering from constant severe headache, something of the aged in her facial expression, with a moderate panniculus, upper part of the body most developed, never having menstruated and without mammary glands. From behind each ear a prominent fold of skin extends to the shoulder, greatly widening the neck. These characteristics signify a dysfunction on the part of the anterior pituitary, combined with the manifest inactivity of the sex glands. All her life the patient has suffered from diarrhea due to achylia gastrica. The author believes this prolonged alimentary disturbance has reacted upon the functioning of the endocrine system. The condition, therefore, he considers a manifestation of pluriglandular atrophy, digestive in origin, whose evolution has been arrested in some of the endocrine glands and not in the remainder. Treatment is problematical. Radiography shows that the epiphyses of the long bones are united in the lower limbs, but not in the upper ones: it is a question whether the administration of ovarian and pituitary extracts, which is indicated on other grounds, may not cause undue elongation of the arms without increasing stature. It is probable that ovarian transplantation may be resorted to.

Kottmann's Reaction: the New Test of Thyroid Function.—This test, proposed by its originator in 1917, has been compared by G. Etienne, G. Richard, Krall, and F. Claude (*Revue Française d'Endocrinologie,* June, 1926, vol. 4, page 175) with tests in general use. A cubic centimetre of fresh serum, to which is added one fourth of a cubic centimetre of a one in two hundred solution of potassium iodide and three cubic centimetres of a one in two hundred solution of silver nitrate, is exposed for five minutes at a distance of twenty-five centimetres from a five hundred watt mazda lamp. Half a cubic centimetre is then added of a one in four hundred solution of hydroquinone and the changes of color recorded every five minutes as it turns from yellow to brown. The change is accelerated in hypothyroid subjects and retarded in hyperthyroid subjects, as compared with normal serum. Opinion is divided among those who have used the test as to its value. The authors found their modification of it to accord in only seven out of thirteen trials with the results reached by the Goetsch test, the thyroid sign, and estimation of basal metabolism.

Development and Nature of Socalled Toxic Adenomas.—A. E. Hertzler deprecates (*Endocrinology,* March-April, 1926, vol. 10, page 175) partial removal of the thyroid gland. He says: "I have been feeling goitres and sectioning goitres in this community more than thirty years. This experience convinces me that an attempt to distinguish between adolescent, the slightly toxic, and the multilobular colloids is no more sane than attempting to classify the separate weeks in typhoid fever as separate diseases. I can multiply such pictures as the following. A young girl has an enlarged gland, a perfectly innocent thing and will disappear. That the girl was nervous and had dysmenorrhea was unfortunate (thirty years ago childbirth would relieve this; twenty years ago the Beattie operation; ten years ago dilatation, curettage, the stem pessary, or the removal of a 'chronic appendix'). But the goitre was innocent. With the passing of years and the advent of pregnancy the goitre reappeared, uniform in outline, soft or elastic in consistency, otherwise innocent. Intimate acquaintances noted the patient was more irritable than formerly, but, she being possessed of a husband and children, who needs to look to the thyroid as a cause of nervousness? The goitre shows an irregularity here and there and in time becomes lobulated. It is now a lobulated colloid. Sometime between thirty-four and fifty-five the patient notices some shortness of breath, irritability, loss of weight, and perhaps more serious symptoms. But there are the children in society and the enlarging prostate, all calculated to disturb mother's rest. The symptoms increase and anorexia supervenes with rapid emaciation, and mother is buried innocent goitre and all, now these thirty years ago. We know now that the demise of the hypothetical case was caused by a toxic adenoma. But we are as ignorant as ever as to the actual cause of death. Symbolized complacent ignorance!" "The important fact is that the whole gland of the toxic adenoma is diseased. The histology indicates that it is injured beyond repair. According to present methods, we remove a part of the diseased tissue. This is unsurgical. The demands of ideal surgery dictate that the whole of the diseased tissue shall be removed. The question is, are we able at this time to meet the ideals in the surgical treatment? The result is a myxedema. This myxedema can be controlled by the use of thyroid extract. There are no more comfortable persons than those myxedemics who take their grain a day. This is better than to allow the patient to depend on the remaining part of a hopelessly crippled gland. Besides, the technical difficulties in removing all the gland are by no means small. Something more exact than the grab and cut method commonly employed in thyroidectomy must be adopted. The recurrent nerves and the parathyroids must be spared." "The production of myxedema is still considered an actionable offense, and no one cares to publish evidence for the use of the attorneys for the plaintiff. The law requires the surgeon to exercise the skill common to the profession in his environment. To do better than the average is as great an offense as to do worse."

Goitre: Current Errors in Etiology and Treatment.—Among the errors enumerated by I. Bram (*Endocrinology,* March-April, 1926, vol. 10, page 181) are these:

That we can dispense with the major portion of the thyroid gland is a fallacy employed daily by thyroidectomists.

That goitre is necessarily a disease of the thyroid gland is not true. It therefore must not be treated as a local condition. With few exceptions, all goitres begin as local expressions of disturbances elsewhere in the economy. In regions away from goitre belts simple hypertrophy and colloid goitre are usually not due to lack of iodine, but to the premenstrual status, adolescence, pregnancy, heredity, focal and general infections, intestinal intoxication, pelvic neoplasms, and other conditions away from the thyroid gland. Untreated thyroid swellings of this sort occasionally disappear spontaneously. Most often, however, they persist, and in the course of time pathological changes within the thyroid may so change the mass as to give rise to adenomata or cysts. Thus we now have a kind of local condition requiring thyroidectomy.

That there are two kinds of goitre, simple and toxic, is another common misconception.

That basal metabolic tests are infallible is an error usually entertained by the enthusiastic laboratory man who has not sufficient opportunity to observe the human being under the strain of thyroid dysfunction or of Graves's disease.

That all goitres require surgery is an error that leads to unnecessary thyroidectomies and destruction of confidence of the laity in the medical profession.

That the medical treatment of goitre consists in the administration of iodine is a fallacy responsible for more goitres than have ever been seen before.

The keynote to success in therapeutic management is strict individualization with the administration of such measures as qualified rest, diet, medicaments, occasionally electricity, and psychotherapy permeating treatment in all directions. Having eliminated all discoverable causes, these measures are employed in suitable quality and quantity by the properly experienced internist for the proper length of time. In the event of unequivocal cooperation on the part of patient and household complete permanent recovery occurs within from six to twelve or fourteen months. Such a patient, taught how to eat, how to sleep, how to rest, how to work, and even how to think, is permanently restored to health.

Mammary Organotherapy.—Moderate success was attained by H. Vignes (*Revue Française d'Endocrinologie,* June, 1926, vol. 4, page 165) in the use of mammary extract in fifteen patient s with menorrhagia or metrorrhagia. Two received no benefit, six were temporarily improved, and in seven the amelioration was lasting. He does not think that mammary extract acts by antagonizing the ovary, nor by direct effect upon the uterine muscle or bloodvessels, but rather indirectly through the adrenal glands. Adler, Schiffmann and Vystavel, and Manzi have all observed decided hypertrophy of the adrenals, both cortex and medulla, after experimental injection of mammary extract. It is this hypertrophy and the resulting increased secretion of adrenalin by which he explains the hemostatic effect obtained.

Effect of Posterior Pituitary Extract on Intestinal Peristalsis and Constipation.—This effect is very apparent, say P. Carnot and E. Terris (*Paris Médical,* April 3, 1926), on radioscopic examination. The medication produces colic and copious evacuations, which empty the colon completely. The most energetic, violent, and rapid results follow venous injection in cases of occlusion, of intestinal paresis, of pronounced dyschezia of the sphincter. Muscular injection is more simple, but leads to less energetic, though to remarkable results: it is suitable chiefly in cases of chronic intestinal stasis. The simplest route is by oral administration, affording excellent results in habitual constipation. It renews intestinal tonus and reeducates the musculature of the lower intestine.

Goitre in Chronic Intestinal Stasis.—A. C. Jordan (*International Journal of Medicine and Surgery,* Vol. XXXIX, No. 2), says that though some may question whether all diseases of the thyroid gland are toxic in origin, he has always found profound stasis on x ray examination, while his patients often exhibit other end results of stasis.

As to treatment, surgery may be necessary for a thyroid cyst or tumor or to deal with chronic enlargement of the whole gland, though x ray exposures of part of the gland give good results. In thyroid degeneration the failure of the thyroid hormone can be made good by carefully dosed administration of thyroid gland extract. This, however, must be regarded as a temporary measure; the main treatment must be directed to the relief of stasis and of its attendant toxemia. The thyroid gland is rarely degenerated so completely that it is no longer capable of recovery.

Value of Iodine in the Surgical Treatment of Exophthalmic Goitre.—Edward P. Richardson (*Boston Medical and Surgical Journal,* June 10, 1926), says that in general the use of iodine in exophthalmic goitre has the following temporary effect. Within a day or two after its administration a lessening of the patient's restlessness and emotional instability occurs. The pulse slows and the metabolic rate falls, these changes usually being obvious within three days and reaching a maximum within eight to fourteen days. The flushing of the skin and the stare charactertistic of the disease diminish. Coincidentally the patient recognizes a definite symptomatic improvement, a diminution of nervous tension, a quieting of the heart action, and an increased sense of well being. The reality of the improvement is shown by a tendency to gain in weight. If the patient is in an acute toxic crisis, such as formerly often proved fatal, the vomiting and diarrhea cease, other symptoms are relieved, and a definite remission is instituted.

The degree of benefit obtained by iodine varies in differenet persons. In some cases the basal metabolic rate drops to within normal limits; more frequently it persists at a moderate elevation. In general we may say that somewhat less than half the cases show a marked remission, another third show definite improvement, while in the remainder the effect is slight or absent. Apparently no patients are made worse during the short period of treatment recommended.

The surgical treatment of exophthalmic goitre has been profoundly influenced by the use of iodine before and after operation. Anxiety in regard to postoperative toxic reaction and the necessity for frequent resort to multiple stage operations have been largely done away with. But there are two possibilities of harm from the use of Lugol's solution. The first lies in the indiscriminate giving of iodine to patients with enlarged thyroids. The second is that operators may be led to believe that preliminary use of iodine has solved the problem so that cases of exophthalmic goitre may be treated with as little respect as an ordinary neck dissection. Although iodine has contributed greatly to the safety of operative procedures, this is far from the case. There is still the necessity for careful selection and preparation of cases, and for a conservative estimate of how much surgery a given patient may stand.

In the discussion of this paper Frank H. Lahey stressed the point that the promiscuous use of iodine results not only at times in diagnostic confusion, but also at times in danger. He feels sure he is seeing more and more adenomatous goitre probably made toxic by iodine having been promiscuously prescribed. The type of goitre had not been determined before advising the use of iodine and the administration of iodine in adenomatous goitre is distinctly dangerous.

Goitre in Children in New York City.—Frances Cohen (*American Journal of Diseases of Children,* May, 1926) finds from a survey of 11,084 school girls and 783 school boys in New York City that:

1. The incidence of simple goitre in school children and in the older group of women, and the investigation into the conditions of iodine intake which determine endemic centres of goitre, do not justify a conclusion that New York City is an endemic centre of goitre. The mild sporadic cases of simple goitre which occur among school children seem to be dependent on a relative insufficiency of iodine, due mainly to a physiological cause, namely, puberty.
2. Thyroid enlargements occur in New York City about three times more frequently in girls than in boys.
3. With the girls the percentage of incidence of normal glands seems to vary inversely with the degree of activity of the menstrual cycle.
4. Simple goitre among children in New York City reaches its peak at puberty, between the ages of thirteen and fifteen in both girls and boys.

The mild cases of simple adolescent goitre observed among children in New York City seem to show, in the case of girls, a distinct tendency to spontaneous regression after puberty; in that of boys a complete regression.

The findings of this survey do not justify a recommendation for the adoption of a general municipal or school administered prophylaxis as a public health measure in New York City.

Observations on Goitre in Children.—H. Leslie Cronk (*British Journal of Children's Diseases,* January-March, 1926) finds that some factor seems to exist "which affects the tonsils in such a manner that the rise in prevalence of enlarged tonsils coincides with a diminution of goitre prevalence, and exerts such an effect on the latter that the enlarged tonsil rate at times overrides the effect of increased metabolism needed for increased body weight." The writer has no clue as to the nature of this factor. This short paper includes three charts showing comparative charts for boys and girls from the ages of four to fourteen.

Goitre Incidence in New Jersey School Chidlren.—Herbert S. Reichle (*Archives of Pediatrics,* May, 1926) in examining school children in Irvington, N. J., corroborates the interesting findings of Goldberger and Aldinger that in nongoitrous regions there is a high percentage of "physiological goitre" among girls while boys have a much lower percentage. It seems as if the rise in curve between the ages of nine and eleven is due to the influence of adolescence. The percentage falls off rapidly after the age of sixteen with both boys and girls. Treatment with iodine does not materially aid and the author states he has "never witnessed any reduction in the size of these adolescent goitres though the cases were carefully followed up through months by weekly measurements."

Defects in the Membranous Bones. Diabetes Insipidus and Exopthalmos.—Because of the rarity of the case and the fact that the condition is noticed only in children, Bernard S. Denzer (*American Journal of Diseases of Children,* April, 1926) reports an instance of bone lesion primary to diabetes insipidus. It has been assumed that bone lesions which permit bulging at the occiput and depression at the vertex of the skull may distort the pressure at the base of the brain enough to disturb the function of centres situated there. This point of view has been suggested at least by Grosh and Stifel and is not novel, the writer says.

Exophthalmos also seems to be an incidental and not an essential lesion, due probably to a defect in the bones of the orbit.

SYPHILIS

Bismuth Treatment of Syphilis.—Irwin C. Sutton (*American Journal of Syphilis,* January, 1926) states that bismuth treatment is indicated in the treatment of syphilis when the patient becomes intolerant to arsenicals and in the cases rebellious to mercury and arsenicals. It can also render good service where mercury and arsenic have already proved useful and in syphilis of the nervous system. Bismuth is also well supported by a badly damaged kidney and liver, and albuminuria and icterus have been treated without incident.

The association of the arsenobenzenes with bismuth presents the advantage of building up the general state and of performing a drastic offensive against syphilis. It is possible either to practise mixed treatment systematically, to prevent the appearance of stomatitis, or only to give the arsenicals when intense pigmentation or inflammatory phenomena herald a more serious stomatitis. The possibility of an energetic antisyphilitic treatment is a great advantage, particularly in the early stage of syphilis. One can give a total weekly injection of three cg. of the tartrobismuthate and a weekly injection of 0.6 to 0.9 gm. neoarsphenamine, 0.4 to 0.6 gm. of sulpharsphenamine, the same for silver arsphenamine, or 0.2 to 0.4 gm. of arsphenamine. The bismuth and the arsenobenzene may also be mixed in the syringe.

Bismuth treatment may be given intramuscularly, intravenously, or orally. It is of the utmost importance to watch the patient for any signs of intolerance after treatment has been begun and to look for conditions which might favor complications. It is necessary to practice: 1, oral and dental examination for infection and stomatitis; and 2, urinary examination for the presence of albumin.

The question of dose resolves itself into a consideration of the quantity of bismuth given at each injection and the number of injections and frequency in each series of treatment. Usually the dose is given twice weekly. The repeated weaker doses are preferable and expose the patient less to the danger of stomatitis. These are, however, more for ambulatory patients. In infants the doses will evidently be weaker. Congenital syphilitic children are also benefited by bismuth. The general precepts laid down for the treatment of syphilis are: 1, treatment as soon as possible after the diagnosis has been confirmed; 2, a rapid healing of developing lesions and the production of a substantial social prophylaxis; 3, to obtain rapid healing as evidenced by the seroreaction.

For abortive treatment, one gives a series of twenty injections to the rate of three a week if possible, corresponding to a total dose of 0.6 gm. of bismuth metal. The Wassermann test usually becomes negative soon. A second series is given three to four weeks after the first. If the Wassermann is negative, one should reduce the injections to two a week.

Late cases may be affected profoundly and for a long time usually by insoluble salts given intramuscularly. The duration of treatment and the number of series of injections depends on the precocity and on the power of treatment at the beginning and the regularity of the treatment which followed. Concurrently with bismuth treatment the administration of a sulphur treatment is practiced sometimes with the idea that the sulphur exerts a favorable eliminative action on heavy metals of the atomic weight of mercury and arsenic.

The study of the comparative value of the different bismuth compounds is important. The following insoluble compounds have been recommended: bismuth oxide, quinio-bismuth, precipitated bismuth, bismuth oxychloride, and bismuth salicylate. The soluble compounds are: ethylene diaminobismuthogallate, tartrobismuthate and citrate, and sodium bismuthogallate. Colloidal bismuth is the least toxic and it can be given intravenously.

The author has found the following line of treatment of the utmost value in early syphilis:

1. Arsphenamine in doses of 0.3, 0.5, and 0.5 gm. in the first nine days.
2. Five more injections of arsphenamine at the rate of 0.4 gm. each week.
3. Begin bismuth injections of 0.2 gm. twice a week after the fourth intravenous injection of arsphenamine, and continue until sixteen have been given.
4. The second course consists of six injections of arsphenamine, 0.3 to 0.4 gm. and a continuation of the bismuth injections at the rate of two a week until the end of the course when a rest of four weeks is given.
5. The bismuth is stopped for four weeks when, if there are no signs of intolerance, a second course of twelve to sixteen injections is given with the third course of arsphenamine.
6. Four to six weeks rest from arsenic after the second course of arsphenamine when the third course of four to six intravenous injections of salvarsan is given, with also twelve to sixteen injections of bismuth.

A total of 4.5 gm. of arsphenamine and 9.0 gm. of bismuth are thus administered during the first year.

In latent syphilis and all late syphilis, if the patient is in poor condition, or if he has an acute process in some important structure he should have two weeks' preparatory treatment with mercurial inunctions and potassium iodide before bismuth and the arsphenamines are given. Neo, silver, or sulpharsphenamine is used thereafter according to the patient's condition for six weeks, and bismuth injections in a course of twelve to sixteen. After the course of arsenicals is finished a rest from that treatment is given for from three to six months, with a course of five to ten bismuth injections in the interim, when the course is repeated.

In Wassermann fast and Wassermann resistant cases bismuth is especially useful in reducing the seroreaction. Especially good results are obtained from the combination of a new arsenical with it.

Generally speaking, patients with syphilis of the central nervous system should first receive rigid treatment with arsphenamine and bismuth after preliminary preparation with mercury and potassium iodide, before special procedures are resorted to. If combined intravenous and intramuscular treatment is of little avail, tryparsamide intravenous injection of colloidal bismuth, and intraspinal therapy may then be used.

The Vernes Flocculation Test as an Accessory Serological Guide in the Combat Against Syphilis.—Adelaide P. Bayles, Adele E. Sheplar and Ward J. MacNeal (*American Journal of Syphilis,* April, 1926) state that the Wassermann test, as it has been modified by American workers, is, at present, considered to be the most useful serological guide in syphilis. They believe, however, that the flocculation test of Vernes offers a most useful supplementary diagnostic test to be employed in conjunction with the Wassermann. The Vernes test is of especial value as a guide in the management of old, latent or treated syphilis.

It is a well known but still not adequately appreciated fact that eradication of the syphilitic virus, if it is ever possible, is to be attained more readily when thorough treatment is initiated at an early date after infection. Where the infection has persisted for several years the treatment with drugs at present in use often appears entirely unavailing to produce a serological response even after a period of years. In those patients in whom the virus has become established in the central nervous system, the aortic wall or other site especially favorable to the parasite, attempts at eradication would appear, in general, to be futile. Conservation of vitally important structures rather than the goal of a negative Wassermann should here be the guiding purpose.

Vernes readings are analogous to temperature observations, and monthly tests should be made during the course of treatment. They give a fairly good idea of the response to treatment. Even though the Wassermann may be misleading, it should not be discarded entirely. The chief reason why the Wassermann is misleading is that the report of the result can be readily misunderstood by the uninitiated, especially when the readings are intermediate between four plus and negative. A patient may have a four plus Wassermann when actually syphilis is a negligible factor in his present disease. On the other hand, many are inclined to give too great attention to it and treat the patient for syphilis when his dangerous disease really requires something else.

The Vernes flocculation reading evidently depends in part at least, upon other features of the patient's blood than does the Wassermann reading, especially in latent and in repeated syphilis. Furthermore, the Verness test, properly performed, gives a standardized reading, analogous to the reading of a certified thermometer. Very high Vernes readings, 0.30 or above, point unmistakably to actively destructive syphilis and at once challenges the physician to locate the site of this activity by other diagnostic methods. Low readings, on the other hand, indicate, not necessarily the absence of syphilis but rather the absence of destructive activity. Unless it is quite high, 0.15 or above, the single Vernes test is not of much help in diagnosis of the presence of syphilitic infection,

but with repeated tests after a provocative arsphenamine injection or several such injections, the Vernes reading shows definite fluctuation in practically all syphilitics, often tending to rise in long-standing cases, and to fall at once in more recent infections, whereas in non-syphilitics its value is approximately maintained.

It is proposed that the systematic treatment of syphilis be coupled with an elaborate and definite serologic control consisting of monthly tests of the blood Wassermann and the Vernes methods and semiannual examination of the cerebrospinal fluid; such serologic control to be continued for at least six months after medication has ceased, with subsequent periodic health examination to the end of life.

Newer Viewpoints in the Treatment of Syphilis.—A study and analysis of the present status of syphilological thought, as it is expressed in clinical records and the literature, justify Moses Scholtz (*American Journal of Syphilis,* April, 1926) in drawing the following inferences:

1. The common conception of therapeutic control of syphilis is too dogmatic and schematic and is based entirely on the chemotherapeutic and serological principles, to the complete submersion of clinical and biological aspects.

2. The value of the Wassermann test, completely dominating and controlling the clinical judgment of the observer, is overrated by the average medical man as a diagnostic and therapeutic guide.

3. Serological limitations of the Wassermann test are testified to by persistent efforts of serologists to find other serological substitutes, such as precipitation tests.

4. Precipitation tests, particularly the latest Kahn modification, give promise of supplying a substitute or alternate test for Wassermann.

5. The specific treatment, particularly arsenic, is absolutely curative only in the early stages; then it is our best weapon for an effective abortive treatment. If an early sterilization is not obtained, its effectiveness is dependable so far as symptomatic control is concerned, but as to complete cure it is much less certain.

6. The specific treatment with arsenic, mercury and bismuth is potential of serious toxic reactions in individual cases and should not be given routinely and indefinitely on the strength of positive Wassermann alone in the presence of persistently negative visceral, cardiovascular, and neurologic clinical findings.

7. The chemotherapeutic method of the control of syphilis is subject to the charge of onesidedness and biological inadequacy, as it ignores and even counteracts the function of natural defense mechanism.

8. The nonspecific therapy of syphilis—malaria inoculation, milk injections, serum therapy, etc., offer a new therapeutic principle of unknown significance at present.

9. No definite standard of cure in syphilis can be accepted at present. The clinical valuation of the case should be regarded of equal value with serological findings.

Cardiovascular Syphilis Following Adequate Early Treatment of the Original Infection.—J. Rowan Morrison (*Urologic and Cutaneous Reveiw,* April, 1926) states that not many years ago the idea prevailed that syphilitic individuals properly treated for a sufficient length of time were unlikely to have involvement of the cardiovascular system, and that those who were treated not at all or inadequately were quite likely to develop the aftereffects mentioned. Both the foregoing propositions have been proved fallacious or at least uncertain. Some undoubted cases of syphilis without treatment may pass through its various phases to an ultimate clinical cure; whereas in others, regardless of the manner of treatment, complications and sequelæ develop. This explanation is unsatisfactory, however, when one remembers that complications quite as frequently follow mild or socalded benign syphilis as the more malignant types.

It was formerly quite generally thought that cardiovascular and neurosyphilis were invariably late or socalled tertiary manifestations of the disease, but it is now well understood, however, that there are no time limits which govern the progress of the various phases of the disease, and involvement of the cardiovascular or central nervous system may occur at any period in the course of the affection. Some authors believe that syphilis is a disease of the vascular system from the beginning of spirochetal invasion, and it is certain that involvement of the lympathic structures occurs soon after the spirochetal invasion. The consensus of opinion appears to be that individuals properly treated in the early stages of the disease would be unlikely later to develop aneurysm or cardiovascular syphilis. However, the author has seen several cases in which syphilitic aortitis developed despite three years of treatment with mercury and potassium iodide. The cardiovascular manifestations developed between eight and twenty years after the original infection.

In considering the treatment of syphilis the development of cardiovascular changes must always be borne in mind, and this applies to the modern intensive methods as well as to the older treatment. The most important practical points for consideration are: 1, whether it is possible by the early application of the old fashioned treatment with mercury and the iodides, or for that matter even by the modern intensive methods with arsphenamine and mercury, to prevent the development of cardiovascular syphilis, and 2, whether the heart and aorta as well as the central nervous system may not be involved before the secondary manifestations of syphilis appear. Whether or not individuals treated by the newer methods will enjoy greater freedom from cardiovascular and neurosyphilis cannot be foretold.

Chronic Indigestion and Syphilis.—Albert Crance (*Urologic and Cutaneous Review,* April, 1926) found that in approximately ten per cent. of latent cases of syphilis there are stomach symptoms. One of the first symptoms of a spinal cord lesion of latent syphilis is apt to be indigestion in some form or other. There may be nothing else associated with it symptomatically, and yet how often is the etiology of indigestion gone into thoroughly? Refractory cases of indigestion are usually subjected to gallbladder and appendix operations before the diagnosis of syphilis is finally made. Stomach trouble, associated with a history of a "previous nervous breakdown" is almost a constant fact in these histories. In all such cases a complete physical examination, especially for signs of tabes, should be made. Interpretations of the blood Wassermann reaction are absolutely essential and a spinal fluid Wassermann is often necessary.

In making differential diagnoses between the stomach symptoms of syphilitic disease and those due to other causes, we must first consider that there are two types of pathology in syphilis which produce stomach symptoms. The first is that of specific ulcer, which may occur in the stomach or duodenum, due to the disease itself. Secondly, we have the cases with gastric symptoms which are caused indirectly from involvement of the spinal cord, which throws its reflex into the vagus network and consequently gives us chronic indigestion, or often acute indigestion, as a symptom.

Principles of Treatment of Wassermann Fast Syphilis.—Leon B. Cowen (*Urologic and Cutaneous Review,* April, 1926) states that obviously it is more rational to have an active, useful, and clinically healthy patient with a positive Wassermann than to have a crippled, helpless invalid with a negative one. In the handling of Wassermann fast syphilis it is necessary: 1, to understand the biological factors which cause the condition known as wassermann fast; 2, to know the action of the various antisyphilitic drugs upon the human organism, giving them their proper evaluation; 3, to prevent the Wassermann fast state from occurring, if possible; and 4, to correlate these facts into a logical system of treatment, applied to the biological needs of the individual patient.

To understand the biological factors underlying the Wassermann fast state of syphilis, we must study the patient by means of a complete physical and neurological examination. All foci of infection should be treated. The central nervous system should receive special attention and a lumbar puncture should be done.

The arsphenamines are of real value, this applying especially to intramuscular injections of sulpharsphenamine in late syphilis, central nervous system involvement and in Wassermann fast syphilis. Mercury, bismuth and the iodides act only indirectly by stimulating the protective mechanism of the body.

The ideal treatment of syphilis is to rid the patient of all physical signs of the disease and to obtain a negative Wassermann. The patient should be given the maximum treatment that he can endure without injury. This intensive treatment must not be so vigorous as to overwhelm the body cells completely and prevent the normal elaboration of antibodies. To continue to give the patient his maximum treatment when the Wassermann remains persistently positive, is not only useless but dangerous. Arsenic, mercury, and bismuth are potentially protoplasmic poisons. Small doses given over a long period of time produce destructive lesions in the liver and kidneys.

In Wassermann fast syphilis the difficulties of complete sterilization are increased and the treatment is more complex than in the early stages, as the spirochetes are latent in the cardiovascular and nervous systems and periosteum. The patient's health suffers from the drugs poured into the body in the effort to eradicate the spirochete. It is then the physician's duty not only to control the infection but also to conserve the health of the patient. Mixed therapy with drugs adapted to reaching hidden foci of infection is indicated.

The Wassermann test is an index of infection of the body with the spirochete. A positive Wassermann implies syphilis whether physical signs are present or not. A single negative Wassermann does not rule out syphilis. The serological examinations are done for two purposes: to make a diagnosis when physical signs are vague or absent, and to determine a cure. A careful history of the patient's treatment up to the present time will often give a clue as to the cause of failure to obtain a negative Wassermann. To repeat the course of treatment after a thorough course of specific treatment is dangerous.

If no treatment has been given for a period of over six months, eight injections of neoarsphenamine may initiate the course. Three courses of neoarsphenamine and mercury given over a period of a year suffice. Each course consists of neoarsphenamine 0.6 gram given weekly for eight weeks and bichloride of mercury in oil given biweekly for six weeks with a four weeks' rest between courses. If the Wassermann taken one month after the cessation of treatment is positive, the patient may be called Wassermann fast. Further treatment along these lines is useless.

The problem must now be attacked from the angle of immunology. In susch cases, sulpharsphenamine intramuscularly in doses of 0.3 to 0.45 gram. given in 1.5 c. c. sterile distilled water, is the arsenical of choice. After a rest of one month, eight injections are given at weekly intervals. Following this, bismuth salicylate, grains 2, is given twice weekly for six weeks, completing the course. Bismuth acts more powerfully than mercury on the body cells to help destruction of the parasites and is useful in all resistant cases of syphilis. After this the patient is told that the disease is arrested but not cured and he is given forty mercury rubs. He must return after three months and if the Wassermann is then positive, he is reexamined and the spinal fluid is tested. If the latter shows a positive Wassermann, a course of sulpharsphenamine and bismuth is again given. Henceforth, bismuth and mercury should be given by choice. One course of bismuth salicylate, twelve injections, and one course of mercury, bichloride in oil, biweekly, or two courses of inunctions during the period of one year, will keep the infection in check.

To raise the general immunity of the body, nonspecific protein injections with milk or gonococcus vaccine may help. This form of treatment is still in the experimental stage.

Recurrent Early Syphilis.—Charles C. Dennie (*American Journal of Syphilis,* April, 1926) applies the term "recurrent early syphilis" to those cases that present cutaneous syphilitic manifestations secondary in character, following the initial course of treatment with the arsphenamines. These manifestations make their appearance shortly after the course is ended. The great majority recur within the first six months and a few show active syphilitic manifestations during intensive treatment. Recurrent syphilides cannot be differentiated from the usual secondary eruptions, except that they are usually more intensified and are prone to take on abnormal characteristics, either in configuration or in distribution. In some instances, the recurrence may be limited to a single lesion, which is sometimes erroneously considered to be a primary sore, and the patient diagnosed as a case of reinfection. Such lesions are alive with treponemas and are very highly infectious.

Recurrent syphilis is caused by the following factors: 1, early insufficient treatment; 2, failure in an abortive cure; 3, the initial treatment with the arsphenamine in the preeruptive and eruptive stages, thus decreasing the patient's immunity; 4, small doses of arsphenamine, spaced too far apart, producing arsenic fast organisms; 5, overarsphenaminizing and undermercurializing the patient.

Recurrent syphilis is prevented by the following measures: 1, Early, energetic, long continued treatment; 2, the use of mercury in the eruptive and preeruptive stages of syphilis for at least three months, after which arsphenamine may be used; 3, arsphenamine should be used in maximum doses at frequent intervals, keeping contraindications in mind; 4, one should keep in mind that mercury is still our best therapeutic agent.

When the actual occurrence has taken place one should use: 1, Old arsphenamine in maximum doses, spaced correctly, until the patient is noninfective; 2, intramuscular or intravenous use of mercury to the limit of tolerance, alternated by courses of bismuth.

Results with Tryparsamide in the Treatment of Neurosyphilis.—Continued observation for a fairly long period has convinced Louis Berg (*American Journal of Syphilis,* April, 1926) of the value of tryparsamide in producing clinical improvement in over forty per cent. of cases that were not selected, observing only the precautions not to take those susceptible to optic nerve damage. Another five per cent. at least were moderately improved by the treatment.

The improvement in the clinical symptoms is not often accompanied by a corresponding change in the Wassermann reaction, as many of the markedly improved patients had a strongly positive Wassermann at the end of treatment. However, in a small group of cases the author was able to change the Wassermann from positive to negative in association with clinical improvement. A large number of cases showed a decided reduction in the cell count from a very high count to zero, or within normal limits.

The use of tryparsamide intensively is indicated in neurosyphilis as with it one may hope to secure definite improvement in a fairly large percentage of cases, and in a small percentage, to achieve a corresponding serologic improvement. The untoward action of the drug can be guarded against by careful routine ophthalmoscopic examination and the immediate cessation, with the institution of eliminative measures, should transitory visual symptoms occur. Clinical improvement was indicated in many cases during the first and second courses of treatment. The treatment should be continued even after decided clinical improvement has taken place. It should be repeated after a rest of several months and five and even six courses may be given without danger to the patient if proper precautions are taken.

PEDIATRICS

Infectious Mononucleosis in Childhood.—Murray Harold Bass (*Medical Clinics of North America,* November, 1925) remarks that infectious mononucleosis is a definite syndrome closely related to glandular fever. Its course may often be quite prolonged; it may take months before the swollen glands disappear and the blood count returns to normal. The nodes are usually not very painful and almost never go on to suppuration. The progress of the disease almost invariably leads to complete recovery.

Infectious mononucleosis may affect people of all ages, but chiefly attacks children and young adults. Males are more often affected than females. It is an illness which usually begins with a sore throat, and therefore is frequently mistaken for socalled grippe. The nasopharyngitis which heralds its onset is not different in any way from the ordinary affection to which so many children are heir, and cultures taken from the throat have shown nothing in particular. Following the pharyngitis, the cervical and other regional lymph nodes become enlarged. They may be moderately enlarged or may reach the size of glands seen in the course of leucemia. In most of the reported cases only the superficial nodes are mentioned. However, the deeper lying nodes may also be involved.

Operative Treatment of Hernia in Infants and Young Children.—Andrew Fullerton (*British Medical Journal,* February 13, 1926) reports the use of the simplest type of a conservative operation for inguinal hernia in infants and young children. The technic is as follows:

An incision about an inch long is made over the upper end of the sac, the cord is isolated, and the index finger of the left hand is passed under so as to spread out the component parts. With light touches of a sharp knife the successive coverings are divided longitudinally and reflected till the sac is reached. The latter can then be separated by blunt dissection with gauze and forceps until the neck is freed as high up as possible, taking great care to avoid injury to the delicate vas. The neck of the sac is then transfixed with a small round needle, tied off with fine catgut, and allowed to retract. In female children it is impossible in most cases to separate the round ligament from the sac, and this structure is therefore included in the ligature occlud-

ing the neck of the sac. In all cases, male and female, it is a wise precaution, just before ligating the neck, to open the sac, so as to exclude the possibility of the presence of abdominal contents. The inguinal canal is not interfered with in any way, and only in a very few cases were sutures placed in the pillars of the external ring. After tying any bleeding vessels the skin wound is closed with a subcuticular silkworm gut suture, the ends of which are tied over a pad of gauze, which is left in position until the wound is quite dry. The suture is then cut about an eighth of an inch from the point where it enters the skin at either end of the wound, and a collodion dressing is applied.

Patients who were operated upon in the out patient department were taken home as soon as they recovered from the anesthetic, and were brought back for observation after two or three days. The author's statistics show conclusively that operations for hernia in infants and young children are as safely conducted in the out patient department as in the wards; in fact, if anything the balance is slightly in favor of the out patient department. Two great advantages are gained by operating in the out patient department:

1. The child, if being nursed by its mother, does not suffer the inconveniences and risk of being weaned.

2. The range of usefulness of the hospital is enormously increased, as the necessary beds are available for other patients, especially in a small children's hospital.

Respiratory Catarrh in Children.—Routine examinations, conducted on young infants, three to six weeks of age, convinced Richard C. Clarke (*Lancet,* October 24, 1925) that at least half of them already had respiratory catarrh. The development of respiratory catarrh probably depends on two main factors: 1, The number and virulence of the catarrhal organisms which attack the mucous membranes; 2, the local resistance of the mucous membranes and the general immunity of the body. From clinical observation it appears, 1, that the very young mucous membrane is deficient in resistance; 2, that after early and repeated attacks, either loses or never acquires an adequate resistance.

The sources of the infection are usually the mother and the germ laden atmosphere. Infection may be prevented by the mother wearing a mask in case she has an acute catarrh when the baby is born. In general, children should be kept away from people with colds and children's parties as much as possible, especially the latter.

Value of Blood Transfusion in the Newborn.—Paul Guéniot (*Bulletin de l'Académie de médecine,* March 2, 1926) calls attention to the powerful effects to be expected from blood transfusion in the newborn owing to the fact that merely twenty mils of blood correspond to one tenth and one hundred mils to one half of the entire mass of blood in the child's body. In twenty premature infants the author, with Seguy, injected ten to twenty mils of citrated blood from two to twenty-six days after birth, on account either of low vitality, a marked or progressive and disquieting loss of weight, or persistent failure to gain in spite of specific treatment where indicated. Some infants had a subnormal temperature, or attacks of cyanosis, or were unable to feed. In sixteen of these infants transfusion was followed by a gain in weight, which began on the next day in ten, on succeeding days in four; and after a second transfusion in two. In eleven out of twelve infants which remained under observation this gain continued progressively. In five hypothermic infants the temperature rose on the day after transfusion and remained close to normal thereafter. In three children attacks of cyanosis ceased, and others were enabled to take the bottle and later nurse at the breast. Excellent results were obtained in the premature infants of three tuberculous mothers, transfused on account of marked or progressive loss of weight. The transfusion supplies the infant not only with erythrocytes and hormones, but also with leucocytes, in particular the polymorphonuclears, in which the blood of the young infant is relatively poor, and which assist digestion and assimilation through their ferments. The donor is usually the mother, unless she has tuberculosis or other infection or her blood is incompatible. The site of injection is the superior longitudinal sinus which, Seguy has found, is reached with least difficulty in these small infants from the posterior fontanelle. The injection should be made slowly. With the head well immobilized and careful procedure, the author anticipates no difficulty in keeping the needle in the sinus. The procedure is not indicated in all premature infants but is the most hopeful measure at hand for those which fail to thrive under usual care.

Fasting as a Cause of Convulsions.—In a paper by Hugh Josephs (*American Journal of Diseases of Children,* February, 1926) attention is called to short fasting periods as a cause of convulsions in children, especially that type of convulsion which is seen at the onset of acute infections. Studies carried out on several children indicate that these convulsions are probably of hypoglycemic origin. The close association of this type of convulsion with the attacks of recurrent vomiting is also brought to notice. As this was a clinical study no attempt was made to discuss the mechanism of the hypoglycemia or the significance of the acetonemia that accompanies the attacks.

Actinotherapy in Pediatrics.—The field of inquiry into the exact manner how ultraviolet rays exert their beneficial effect is by no means exhausted according to J. H. Gettinger (*Archives of Pediatrics,* Vol. 43, April, 1926) and while it is known that these rays are absorbed by the blood, it is not known how it is stored, or in what manner or form it is set free in the tissues. In this respect, the ultraviolet rays resemble very closely the vitamines.

The author's experience in regard to pertussis was that in the majority of twelve cases there was a marked improvement after the first few exposures to the rays, both in the vomiting and in the intensity of the paroxysm. Many patients lost their "whoop" entirely after ten exposures. One child, two and one half years old, lost its whoop after the fourth exposure.

Light and the A-body.—In an interesting investigation of light and the A-body, C. E. Bloch (*American Journal of Diseases of Children,* Vol. 31, March, 1926) is led to the opinion that "light cannot replace the A-body or supply it to the animal organism," although light and the radiant energy of ultraviolet light is essential to various functions of the organism. Two cases of xerophthalmia which are described were not cured by exposure either to the carbon arc light or to sunlight. In plants, however, the light rays of sunlight or the carbon arc light both produce the A-body; the ultraviolet rays are inactive in this respect.

Thyroid Extract "Injections in Certain Infantile Cachexias.—P. Nobécourt and M. M. Lévy (*Presse médicale,* February 27, 1926) report good results from injections of a fluid thyroid extract in large doses in some cachectic nurslings. They injected fifty to 100 milligrams of extract daily for ten or fifteen days. Among the illustrative cases is one of a child two and a half months old weighing 2,750 grams, 310 grams having been lost since birth. Under the thyroid treatment the child was considerably improved, leaving the hospital weighing 3,800 grams; twenty days later the weight was 4,410 grams. A child six and a half months old, admitted weighing 4,800 grams, dropped to 3,670 grams following a severe attack of scarlet fever with complications. The condition being desperate the thyroid treatment was begun and the child left the hospital weighing 4,180 grams. Six weeks later it weighed 5,500 grams.

Chylothorax in the Newborn Infant.—Chester A. Stewart and H. P. Linner (*American Journal of Diseases of Children,* May, 1926) tell of a fatal case of chylothorax in an infant, aged four days, due apparently to a rupture of the thoracic duct. In the amounts given, the oral administration of sudan III failed to stain the fat droplets in the chylous fluid. A golden yellow color of the chylous fluid present the first few days apparently was due to lactochrome (carotin, largely) derived from the colostrum the baby obtained at the breast. Following the injection of sterile congo red into the peritoneal cavity, the dye appeared in the chylous fluid in the pleural sac.

Osteomalacia in Children.—Two cases of osteomalacia occurring in children are reported by Hugh L. Dwyer and Orren S. Eckelberry (*American Journal of Diseases of Children,* May, 1926). Studies on the mineral metabolism indicate that there is a lowered retention of calcium, magnesium and phosphorus. In one patient the calcium loss reached a negative balance. The mother of one patient had a history of six fractures, indicating the probability of bone pathological changes. A brief review of the literature on the etiology of osteomalacia and its relation to rickets is presented.

Flatfoot in Infants and Children.—Philip Lewin (*American Journal of Diseases of Children,* May, 1926) in a compact little article clearly illustrated with diagrams and pictures urges that more consideration be given to the condition of flatfoot among infants and children. There is advice on shoes and foot exercises.

PRIVILEGE OF REFUSING TO DISCLOSE AILMENT OF ABSENT WITNESS

In a personal injury case a physician was called by the plaintiff to testify that another witness, M., was physically unable to be present in court. This was for the purpose of laying a foundation for the introduction of M.'s deposition, taken some time prior thereto. The relation of physician and patient had been established as a matter of law. The physician, after testifying generally on direct examination that M. could not be present in court, was interrogated by counsel for the defendant, who endeavored to elicit the exact nature of the patient's infirmities. Upon his own motion the physician refused to testify in this behalf on the ground that to do so would be to violate a professional confidence. The trial court sustained the witness in his refusal to testify, and the California Supreme Court holds, Darling v. Pacific Electric Ry., 242 Pac., 703, that in so doing no error was committed. The court said: "This is a personal privilege given to the patient, and no one, except in certain specified cases, has the right to waive the same for him. This rule of privilege applies although the patient is not a party to the action in which a disclosure is sought and is not present to object. There was no express or implied waiver of this privilege by the patient in the instant case, and, in the absence thereof, the physician was clearly within his rights in refusing to testify concerning a matter which could not be divulged without a breach of professional confidence." The deposition by the patient did not, it is held, waive the privilege.

CALIFORNIA STATUTE OF 1925 AS TO QUALIFICATIONS OF DRUGLESS HEALERS HELD NOT VIOLATIVE OF FEDERAL CONSTITUTION

In a suit to restrain the enforcement of chapter 10 of the Session Laws of Washington for 1925, which provides for the revocation under certain circumstances of licenses issued to drugless healers, the federal district court for western Washington, Butcher v. Maybury, 8 F (2d) 155, bases its decision denying the injunction upon the following grounds, for which the court cites many authorities.

"The right of a physician to practice his profession is a property right, of which he cannot be arbitrarily deprived. The right is a qualified one, and is held in subordination to the duty of the state under the police power to protect the public health. The police power cannot be stipulated or bartered away. The authorities hold without dissent that it is competent for the Legislature to prescribe qualifications for those who are to practice medicine and thus to assure that they shall possess the requisite character and learning The regulation of drugless healers is a proper exercise of the police power. The regulatory power of the state may be properly committed to an administration board or officer. These regulatory statutes may be made operative on those engaged in practice prior to the enactment of the statutes. The state may change the qualifications from time to time, making them more rigid. The Legislature may prescribe qualifications, both as to character and learning, which will require those in practice to give up their occupation. Legislation prescribing qualifications which a practitioner cannot meet because of conditions antedating the enactment of the legislation is valid. Such legislation does not constitute punishment; it is legitimate regulation. The limitation on the above doctrines is the principle that the regulations must be reasonable and must bear some relation to the service to be rendered by the practitioner.

"The changes in the qualifications of drugless healers, made by the act of 1925, were within the legislative discretion. It is not unreasonable to exact a high school education or its equivalent as a proper standard of general education. Neither is it an arbitrary exercise of legislative power to require a residence course of three sessions, consisting of thirty-six weeks each, in a school of approved standing.

"The power of the state to require a license implies the power to revoke a license which has been improperly issued. Provision for the revocation of such licenses is made by the act of 1919, whose constitutionality is not under attack. The statute in question merely changes the procedure required for such purpose.

"The act of 1925 provides for notice and hearing to a licentiate whose license is proposed to be revoked. He is entitled to the compulsory attendance of witnesses and to be represented by counsel. If the issue is determined against him, he has a right to review the action of the director of licenses in the superior court for Thurston County. This procedure abundently meets the 'due process' requirements of the Fourteenth Amendment."

The statute, it is held, does not deny to the praintiff the equal protection of the laws.

It is not invalid as a bill of attainder, which is a legislative act inflicting punishment without judicial trial.

It is not invalid as an ex post facto law, although the licenses of some practitioners might be revoked on account of inability to meet qualifications prescribed since the liceness were granted.

"A constitutional statute may be enforced so arbitrarily as to violate the right of a party to pursue his occupation, but the presumption is that boards and officers will be actuated by good motives and will act fairly"

The bill contained no allegations to rebut these presumptions.

The statute was also attacked as violative of various provisions of the state constitution. The federal court declined to pass on this contention, since the state supreme court had declined to pass on the conformity of the statute to the state constitution.

INDICTMENT CHARGING SEPARATE VIOLATIONS OF HARRISON ACT

The Circuit Court of Appeals, Eighth Circuit, holds, Daugherty v. United States, 2 F (2d) 691, that under an indictment charging in three separate counts separate violations of the Harrison Act, §2, the contention that each sale should be taken as resulting from the same criminal intent and that the three counts therefore charged only one crime was not sound, because criminal intent is not an element of the crime, and because each count charged a different sale to a different person and on a different day, and if the sales were made as charged they constituted three separate offenses.

CLASSIFICATION OF MINERAL WATER AS FOOD OR DRUG

The Circuit Court of Appeals, Sixth Circuit, holds, Goodwin v. United States, 2 F (2d) 200, that where the consituent drug elements of a mineral spring water are not completely extracted therefrom and transported and sold without the admixture of other elements, but the processes of separation are carried to such an extent that the water can no longer be used as a beverage, but only in small quantities or doses as a medicine, it cannot be classified as a "food," but comes within the meaning of "drug" as used in the Federal Pure Food Act and amendments thereto.

A Survey of Important Factors Leading Up to Our Present Conception of Tuberculosis*

FRANCIS MARION POTTENGER, M.D.
Monrovia, California

Tuberculosis has been recognized as a clinical disease throughout historical times; and until within the memory of those of the present generation it has been looked upon almost universally with utter despair and hopelessness. During the greatest portion of this time it was known only by its advanced symptomatology.

AUENBRUGGER AND LAENNEC

Not until Auenbrugger (1) described percussion (1760) and Laennec (2) began to make systematic use of auscultation (1815) did any one attempt to critically examine the patient. It seems strange to us to realize that physicians had not previously thought of percussing or listening to the chest of tuberculous patients. It seems equally strange that those who percuss and auscultate today do not seem to realize that they can palpate the chest and differentiate all the things that they now do by percussion, and some with much greater accuracy. It seems doubly strange that when Laennec once listened he heard so accurately and defined his observations so well. He created a new era. He lifted clinical tuberculosis out of chaos and started a process of definition which has required pathology, bacteriology, animal experimentation, serology, röntgenography and the most accurate and painstaking clinical study to complete.

KLENCKE AND VILLEMIN

In the early centuries certain Greek physicians considered tuberculosis to be infectious. Galen so considered it. Morton in 1689 taught the infectious nature of the disease. In 1782 an edict was issued in Naples based on a belief in the infectious nature of tuberculosis. It required that bedding and furniture in rooms occupied by those dying of consumption should be destroyed by fire. This was a great advance for the time and, while unnecessarily harsh, it shows a conception of the disease which belonged to a much later era.

Klencke (3) in 1843 was probably the first one to transmit successfully tuberculosis to an animal by inoculating it with caseous material from a necrotic tubercle. To him almost belonged the honor of proving the infectious nature of the disease. But he did not carry his work sufficiently far. He left the honor to Villemin (4) to transmit the disease from man to animal and then by taking material from the tuberculous animal again to produce the disease in a second animal. He thus beyond doubt produced the complete experimental evidence which proved the infectious nature of tuberculosis. This he accomplished in 1865—nearly twenty years before the discovery of the nature of the infectious virus with which he was dealing.

BAUMGARTEN AND KOCH

As there were two between whom the credit for establishing the infectious nature of tuberculosis must be divided, so there are two who deserve the credit for discovering the tubercle bacillus. Baumgarten had seen the tubercle bacillus through the microscope previously to the time when Koch made his epochmaking announcement. Baumgarten (5) had seen it unstained; but Koch (6) with his wide knowledge of dyes had been able to produce a stain which rendered it unquestionably visible. His work was so complete that when he announced the discovery of the bacillus, his experimental proof withstood the scrutiny and attacks of all experimenters and opponents. While Klencke and Baumgarten are important contributors to the proof of the infectious nature and bacteriological cause of tuberculosis, it is to the greater ones, Villemin and Koch, that our homage is usually paid.

INFECTION AND HEREDITY

After the discovery of the tubercle bacillus had offered the final argument to Villemin's work we entered on an era of bacterial domination. The tubercle bacillus was considered the essence of tuberculosis, both in the realm of prevention and in the clinic. The idea of the disease being inherited was swept away, and scarcely a trace of the possibility of hereditary factors having any part in the picture was left. Although this was too sweeping, it has taken nearly half a century even to approach an equilibrium and give heredity its rightful place in etiology.

The interpretation of facts which seem to be indisputable is forcing us now to look upon heredity as offering the only answer to part of the problem of

*Abstract of an address read before the Tuberculosis Institute for Nurses, University of Minnesota, Minneapolis, June 14-19, 1926.

Copyright, 1926, by A. R. Elliott Publishing Company.

tuberculosis as a clinical disease; not the inheritance of the infection but the inheritance of characteristics or qualities of cell and cell action which permit the almost universal infection to become active in certain instances while it is held within bounds in others. While the dictum of the era of bacterial dominance that "there can be no tuberculosis without the tubercle bacillus" is true, we are gradually recognizing that the bacillus alone may only cause tuberculous infection; it does not necessarily cause tuberculous disease. Tuberculous disease implies something different—an inability on the part of the individual to overcome his infection. In present immunological terms this means either a failure to develop or a failure to maintain a sufficient specific defensive mechanism. Observation shows that this factor differs with different individuals, and depends upon his vigor and his reacting powers, consequently upon both his heredity and his environment.

No one can observe tuberculosis carefully without seeing that the ability of different patients to react in the formation of scar and healing differs greatly; likewise the power to prevent the spreading of the process. One person will heal with much scar; another with a small amount. One will make as much progress in recovery in a few months as another in many. This must be accounted for as being due to the total ensemble of the patient's reacting powers; both inherited and acquired, both specific and nonspecific.

TUBERCULIN ERA—INTENSIVE STUDY

Koch (7) noted that, when an animal already tuberculous was inoculated again with bacilli, it reacted differently from what it did when inoculated for the first time. He noted, as a result of the second inoculation, that the animal already infected reacted with an inflammatory process around the previous existing tubercles, and further recognized this inflammation as a part of the mechanism of healing. Shieck saw experimental tuberculosis of one eye protect a rabbit from a later inoculation in the other eye.

Koch grasped more fully than others of that period that healing was an immunity response, and that a primary infection increased the animal's resistance to a later inoculation; and further, that subsequent inoculations had a tendency to produce healing in previously existing foci. He therefore noted, too, all important effects of tubercle upon the organism: first, that it produced immunity; and second, that secondary inoculation acting through the immunizing mechanism already established produced a specific inflammatory reaction about previously existing tubercle which was often followed by healing. Further observation shows that this healing effect is greater where the secondary infection is not too extensive; and that, where the secondary inoculation results in a too severe process, the primary effect is a severe inflammatory reaction at times followed by softening and sloughing. Even this destructive process must be considered as conservative for it is Nature's way of eliminating infecting and toxin producing substances even though the process frequently proves too drastic for the patient.

Koch then set about to find some specific product which would produce the same immunizing and healing response as living bacilli without exposing the patient to the danger of a too severe reaction and a renewed infection. This resulted in the tuberculins prepared by him as well as the many preparations made by others.

In spite of the fact that tuberculin will produce the specific inflammatory reaction which is a necessary part in the healing of tuberculosis the remedy has not come into general use, largely, in my opinion, because of a failure on the part of the profession to understand its action and to master its administration. While tuberculin proved disappointing to those who looked for a specific remedy, easy of administration and perfect in its action, yet directly and indirectly it has been the cause of important contributions to our understanding of tuberculosis. As a result of the discovery of tuberculin and the attempts which were made to employ it clinically, scientific men began laboratory and clinical studies which have been responsible for much of the rapid gain in our knowledge of the disease during the past twenty-five years. Pathologists who had found tuberculosis of little interest before began to study it intently, and clinicians observed their patients more closely and gained a more comprehensive and accurate idea of the clinical manifestations of the disease.

As a result of the diagnostic power of tuberculin, clinicians learned that tuberculosis could be diagnosed before bacilli were found in the sputum; so, the first real early picture of clinical tuberculosis was obtained as a result of its diagnostic use.

The serological aspects of tuberculosis have also been studied most carefully and we have arrived at a better understanding of immunity, not only in tuberculosis but in infections in general, as a result of studies stimulated by the serological reactions. Nor must we forget the impetus that was given to the successful treatment of tuberculosis which resulted from the greater interest in the disease and the more careful observations which date from the tuberculin era.

While, in the minds of many, tuberculin failed, it was a most successful failure, if we take into consideration the increased knowledge of our understanding of the disease and in the manner of successfully preventing and treating it which resulted directly and indirectly from tuberculin. As to its value as a therapeutic measure, the preponderance of opinion does not recognize its value and is opposed to its use. On the other hand, there are a few men throughout the world who have been so impressed with the therapeutic action of tuberculin, because of its power to produce the specific allergic reaction in tubercle which is essential to healing, that they have diligently striven with what seems to them, at least, a degree of success, to develop a method of successfully employing tuberculin in therapy. It is a significant fact that rarely has one, who has learned to employ tuberculin therapeutically, relinquished its use.

VON PIRQUET'S AND RÖMER'S CONTRIBUTIONS

One of the most important and farreaching contributions to the understanding of tuberculosis as a disease was made by von Pirquet (8). When he discovered the fact that the skin of a person once infected by tubercle bacilli is hypersensitive to tuberculin he established a method by which we were able to gain our first real evidence of the extent to which the human race is infected with tubercle. This was

followed by the intracutaneous test of Mendel (9), which was perfected by Mantoux (10).

The surprising outcome of the cutaneous and intracutaneous tests applied to large groups of people of all age periods was the knowledge for which we were little prepared, that nearly the whole population is infected with tuberculosis before the attainment of the fifteenth year. The further important fact adduced from these tests, which was likewise revolutionary, was that there is a difference between tuberculous infection and tuberculous disease. While infection is more or less general, disease is restricted to a comparatively small group. Further inquiry reveals that there are two distinct types of clinical tuberculosis; that of childhood, which is of an acute nature, and that of adult life, which is a chronic disease. From this the important facts were established, through the work of Römer (11) and others, that early infection confers an increased resistance or immunity which offers a certain degree of protection against future metastases from foci already present in the body or from bacilli gaining access to the body from without; that adult tuberculosis is directly related to childhood infection, and that the chronic character of adult tuberculosis is due to the increased resistance brought about by the childhood infection.

Thus our conception of tuberculosis as a disease was greatly modified, and a basis for the better understanding of its problems was established. The true problem as established is not so much to prevent infection, but (1) to prevent massive infection and (2) to prevent infection from becoming clinical disease.

BODINGTON AND BREHMER AND SANATORIUM TREATMENT

Although tuberculosis had caused more deaths than any other disease throughout all the period of recorded history, yet there was no definite concerted attempt to treat it until near the close of the last century. While a few men had appreciated the fact that it was a disease which could best be treated in special institutions, with a special régime, and Bodington of Warwickshire had attempted institutional treatment of the tuberculous before the middle of the last century (1840), yet the first permanent institution for the systematic treatment of tuberculosis was established by Brehmer at Görbersdorf in 1859.

Brehmer developed tuberculosis himself when a medical student in Vienna. He noted something that seemed to have escaped the eyes of most men, viz., that in the postmortem room there was much evidence of healed tuberculosis. He noticed that the lesions which healed were the small ones. He wrote his graduating thesis on the subject, Early Tuberculosis Always Curable. While looking for hope for himself he found it for others.

He believed that tuberculosis was caused by the heart being relatively small, and adopted exercise, particularly hill climbing, as a part of his therapy, the amount of exercise and climbing being carefully adapted to his clinical conception of the patient's needs.

Dettweiler, who was a patient of Brehmer, as well as his assistant for six years, thought he noted that harm was being done to many of the patients by the exercise and climbing; so he advocated rest, and when he left Brehmer he went to the Black Forest and established an institution at Falkenstein (1874), in which one important part of the treatment consisted of long hours of reclining on couches on verandas or in *Liege Hallen*, as they were termed. This was the beginning of the rest cure of tuberculosis, which is emphasized so much in all of our modern sanatoria.

Trudeau established the first sanatorium in America in the Adirondacks in 1884. There, isolated in the wilderness, himself a victim of the disease, he not only made the sacrifice to regain his own health but devised means for aiding others. He there started the first scientific investigations on tuberculosis in this country and maintained until his death a keen interest in and an advisory relationship toward everything associated with tuberculosis—its prevention and cure.

Institutions were established here and there at rare intervals until finally the movement was given great impetus by the German Tuberculosis Central Committee, which began its work in 1896. The subject was furthered by the Tuberculosis Congress held in Berlin in 1899. The movement for public sanatoria made further headway in the early years of this century and the principle that each community should care for its tuberculosis as well as other diseases was emphasized.

The importance of the sanatorium as a factor in solving some of the important therapeutic problems in tuberculosis cannot be overemphasized. The treatment of tuberculosis consists of a definite mode of life under constant control and supervision. This has been worked out by close observation of patients in sanatoria in a manner in which it could not have been done in the home. The measures which are most valuable in the treatment of tuberculosis are so simple that it is difficult for the patient and friends to grasp fully the idea. It is really a life that they must live. In the home with its distractions and interferences it is very difficult for the proper helpful atmosphere and surroundings to be provided.

The greatest number of people who have tuberculosis come from the ranks of the poor, whose homes are ill adapted to giving the tuberculous patient the conditions that he needs and to assist him in carrying out a carefully planned program. The homes of those in better circumstances likewise are rarely much better suited to following out such a program. Many well to do patients, particularly the more wealthy, are in the habit of having what they want, being able to purchase it with money. Now comes something that they cannot purchase. They can only attain it by making the sacrifice. To accomplish this they need as much help as the poor, but of a different kind.

It is equally difficult, if not more so, to adapt the average home of the well to do patient, filled as it is with the joys, gaieties and distractions of everyday life, to the treatment of tuberculosis, than it is that of the poor.

In order to obtain results in a large proportion of patients suffering from tuberculosis, institutions for their proper guidance and control are not only desirable but essential. Getting the patients away from the harmful advice, anxiety and interference of friends, even though it is for only part of the time, is of tremendous value.

THE PRESENT CONCEPTION OF TUBERCULOSIS

Our present conception of tuberculosis may be stated something as follows: An infectious disease which is mildly transmissible, the first infection usually gaining entrance to the body in childhood. This infection, unless the numbers of bacilli causing it are too large, results in the establishment of tubercle, followed by a stimulation of the immunizing mechanism of the individual. From this early focus of infection, unless it heals complete, likewise from new infections from without, repetitions of implantation with formation of tubercle occur, each of which results in increased immunity. A great proportion of these early infections never result in more than local tubercle and heightened immunity; others result in a more extensive implantation and a failure to heal, terminating in clinical tuberculosis. The time between the first infection and the appearance of clinical tuberculosis varies from a few weeks to many years—usually the latter.

Some Notes on Cancer*

VI. Adrift on the Cancer Literature. Impressions of a Clinician

WILLY MEYER, M.D.
New York

"It is very much to be regretted," said v. Hansemann (1) twenty years ago, "that in modern medical papers the historical study of the literature is going more and more out of fashion. Today, if authors have read the literature of the last five or six years, they believe they have done wonders." Still more bitingly remarked Virchow (2) (p. 7) fifty years earlier that, judging by the manuscripts sent him as containing new matter for publication in his *Archive,* the younger generation of investigators of that period "seemed to be familiar with no more than the literature of the last year."

If in those days of the infancy of the cancer literature and the baby years of biological research it was apparently already difficult for busy medical men to keep abreast of the developments in their profession; if to do so was still more of a problem in the first decade of this century, at a time when Jacob Wolff (3) in his textbook on the *History of Cancer* catalogued ten thousand papers on cancer, what shall we say of the present conditions, of the flood of papers on cancer that is coming from all over the world from almost numberless clinics, institutions of learning, research laboratories and private individuals, medical and lay? Thirty thousand papers dealing with cancer proper would seem to be a conservative estimate of the sum total stowed away in libraries, and, if the ramifications into allied fields were figured in, one could not unlikely bring together as many papers as there are possible combinations of the twenty or so aminoacids: a two followed by eighteen other figures (Abderhalden (4) p. 367).

For the clinician the cancer literature of today is simply engulfing; its study not infrequently makes him groan like the pupil in Faust: As dazed I feel from all this learning, as if in my head were a mill-wheel turning. (*"Mir wird von alle dem so dumm, als ging' mir ein Mühlrad im Kopf herum"*), tempting him to drop the whole matter and turn to studies that are less trying.

But then again there is a wonderful fascination about this groping in the dark, about catching a glimpse of the sky here and a ray of light there, about having by some remote chance remark perhaps a thought kindled in one's own mind, about grasping at straws of confirmatory evidence carried by on the flood, about coming up for the third time—and suddenly stepping on what seems to feel like solid ground.

When finally bottom shall have been touched definitely in regard to the etiology of cancer, it would not be surprising to see in the then accepted theory a berth found for some part of almost everything that has ever occupied the medical mind in respect to cancer, due allowance of course being made for means

*Received for publication June 9, 1926.

and methods of investigation, or rather the lack of them in the more remote centuries. There have been keen observers at all times, and the deeper one penetrates into the literature on cancer and related subjects, the more firmly one becomes convinced that there is little, if anything, that can be suggested which somebody else has not in some form or other already said or thought or written. Therefore, when in our articles we sometimes seem to stray off at a tangent and here or there have not the quotation at hand with which to back up our remarks, we always feel consoled in the thought that somewhere in the tomes that have become tombs there surely must lie hidden the missing reference, if one but knew just where to put the finger on it.

Looking back at the considerable time we have lost in studying papers of alluring titles that brought no adequate return, and considering on the other hand the number of important papers probably missed that should have been read and would have been read, if guide buoys had been found on the trackless waste pointing the way to them, the desirability seems to stand forth of a large scale, concerted and organized effort to dig out from the cancer literature and to catalogue the papers of real intrinsic value and accompany each title with a line or two indicating the contained essentials. On being swamped by the vast literary flood one cannot help but wish that, in addition to the many associations for cancer research, there should also exist associations for research in the cancer literature, national as well as international.

Similar thoughts were recently expressed by Williams (5) in an address published in the April 7th issue of the Medical Journal and Record of this year. Williams advised the medical students of the College of Physicians and Surgeons of Columbia University in part as follows: "No great advance is ever made by the unaided effort of one man. . . . The kind of contribution to biology we need now is a summarizing of the data. We are all of us at present too close to the great mass of detailed observation to see its broader implications. . . . Gradually, through the efforts of many workers the more essential phenomena will be separated from the incidental, so that it will be possible for one individual to survey the field without devoting so much of his lifetime to the task as to leave no opportunity for that familiarity with the related sciences which is requisite before a generalization can be made."

To "summarize," to "generalize," that is the course we had from the start mapped out for our own work, stipulating only that it should be done from the viewpoint of ordinary medical conceptions, and stipulating further that we would not go out of the way of any difficulty, but rather would make straight for it, try to bring it out into the light and see what could be done with it; otherwise we were to cast ourselves adrift on the literature without any preconceived notion as to whither the currents might carry us.

To generalize is in medicine a kind of literary work that stands by itself. It does not start from results that lead to deductions, but it starts from deductions that lead to results; it is not the description of experimentally ascertained facts that permit of drawing conclusions, but it is the drawing of the essence from manifold conclusions to get at facts; it does not achieve by technic and methods, but it shuns method in order to achieve; it does not require observation, but it requires cogitation; it does not call for the elimination of the personal equation, but for its intense application; it is, as a matter of fact, in every way the antithesis of the descriptive literary work which it distills.

Encouragement to persist in our course has been found in a remark by Virchow (p. 5) in which he puts the historical study of the literature on an equal footing with other methods of medical research in the following words: "May one man try to make headway by the anatomical investigation of disease states, another one by the clinical observation of morbid processes, a third by pathological and a fourth by therapeutic experimentation, this man by chemical or physical, and still another one by historical research, science is so large that it offers room for the unhindered development of all these several courses, if only they know their place, show an inclination to coöperate and do not consider themselves selfsufficient." So we shall continue to set up the nine pins for others to bowl down, if they like. Maybe they will not make a ten strike and leave one or two pins standing, though perhaps shifted a bit from where we had put them. Such an outcome,—should it happen to come to pass, should but ever so little of truth be discovered in our thoughts and points of view—is almost more than we dare hope for.

We have not gone beyond offering thoughts, and have refrained from going into experimenting, partly because there seemed to be no line of experimentation in animals that would cover what we are aiming at, viz., the whole range of cancer questions summarized; and partly because we conceive of such summarizing of the cancer problem from the point of view of ordinary medical conceptions as experimenting, and for that reason this whole series of articles appears as experimentation. This the more so, because these articles do not rest on a generally recognized basis, but on a selfmade foundation, for, paradoxical as it may sound, with all the vast mass of writings on cancer, there is in reality no cancer literature. Every student has first to create for himself his own literature from the unassorted pile before he can get down to real work.

Speaking from experience, should the average clinician embark upon an extensive study of what by courtesy is called the literature on cancer and related subjects, we venture to say, as mentioned above, that it will not be long before it has made him feel dizzy and nonplussed and discouraged, without apparently a redeeming feature about it. For the nature of the literature on cancer is such that, according to inclination, the same thing can be proved black and can be proved white, with plenty of good names to back up either color. But if he perseveres and manages to fight off the temptation to quit, if he does not mind leading the life of a hermit, burning no end of midnight oil and, may be, his own candle at both ends, eventually the time may come when he finds himself in communion with the great minds whose life work has been laid down in the literature, when he rises to thinking through their minds and feels himself lifted to undreamed of, spiritual heights. The joy of such fleeting moments makes up for all the previous gloom. But even this small cup of gladness is not without its bitterness, because if he wants to be

honest with himself, he will have to confess that, like the cancer cell, he is merely passive.

Fever

GEORGE S. BEL, M.D.,
New Orleans, La.

Fever is undoubtedly one of the most frequent pathological conditions for which the practitioner of medicine is consulted, and upon him devolves the responsibility of determining its causative factor and clinical significance.

Fever may be defined as a host reaction to an injurious agent, in the course of which process the normal physiological function of the heat regulating mechanism becomes altered. We must not regard fever as a result of increased heat production but rather as a retention of heat; in other words, it is a condition in which the function of the heat regulating centre is disturbed. During hyperpyrexia, the body gives off more heat than it does normally, but dissipation is not proportional to production, therefore the temperature of the body rises.

While bacteria or their products are by far the most frequent cause of this pyrexial reaction, they are not the sole cause; other organic and inorganic poisons may occasion fever. In addition to disturbances of the heat regulating mechanism, any excessive activity or increased function of body tissues occasions more heat production *per se.* Thus, all inflammatory responses, immunity production, and tissue proliferation that have to do with repair, may of themselves cause the body temperature to become elevated. Such increased activity on the part of somatic tissues, combined with disturbances in the heat regulating centres, seems adequately to explain the occurrence of fever. Since fever is a process concerned with heat production, it is generally agreed that during its course oxidation is increased; carbohydrate metabolism is rapidly depleted; water is retained in the tissues; salt excretion is frequently reduced, and the metabolism of other substances undergoes alteration. There is also a constant destruction of tissues which gives rise to an autopoison, thereby increasing the disturbances to the tissue complex.

Fevers for the purpose of diagnosis may be classified clinically as of short and long duration, and these may be further subdivided into fevers that are intermittent and remittent. We may also speak of infectious and noninfectious fevers. With regard to fevers of short and of long duration, we usually consider a fever that lasts not more than two weeks as one of short duration, and one that lasts for a longer

period, whether it intermits or remits, as a fever of long duration.

On the basis of etiology it is erroneous to state that any specific microorganism or its poison produces a fever of short or long duration, since it is a well known fact that the same microorganism may at one time give rise to a fever of short duration and at another time to a fever of long duration. To elucidate this point we may call attention to that common injurious agent, the streptococcus, which under certain conditions of localization after tissue invasion, gives a fever of short duration, whereas when its invasion is generalized, the fever is usually of long duration. The same can be noted with practically all of the pyogenic microorganismal agents. Generally speaking, it is the rule that injurious agents which occasion exudative host reaction cause fevers of short duration, while injurious agents which give rise to tissue proliferation as the main host reaction cause fevers of long duration. For example, the staphylococcus, Bacillus pestis, Bacillus influenzæ, Bacillus diphtheria, the pneumococcus, the gonococcus, the meningococcus, are all pyogenes producing an acute inflammatory reaction; the fever in these infections is of comparatively short duration. On the other hand, bacillus tuberculosis, Bacillus lepræ, Bacillus typhosus, Treponema pallida, the blastomycetes, are injurious agents exciting tissue proliferation; here the occasioned fevers are of long duration. In the exanthemata, the fever may be of short or long duration, depending upon a number of factors. If it is a pure infection, the fever is of short duration; in the event of complications which so often occur during the course of such conditions, the fever may become one of long duration even when the complication is the result of secondary pyogenic infection. Thus, uncomplicated measles runs its course in eight or ten days; when the disease lasts longer than this it indicates a secondary superimposed infection, usually of some part of the respiratory tract. Further, this common complication of measles may induce toxic alterations in important internal organs such as the kidney, with a resultant continuing fever.

It may be stated as a guide for practitioners of medicine that the common infections that occasion fevers of short duration are as follows: Exanthemata (uncomplicated), all pyogenic infections, particularly when localized, such as acute bronchitis, acute tonsillitis, acute pharyngitis, diphtheria, erysipelas, appendicitis, and pelvic infections. Here it must be recalled that there are certain pyogenic infections that give rise to fever of short duration even where there is a general blood stream infection at one time or another during the course of the disease; as such examples we may mention certain of the pneumonias, pneumonic plague, glanders, etc.

It is not necessary to lay much stress upon fevers of short duration as their characteristic course and salient symptoms enable the physician to make a reasonably sure diagnosis. However, occasionally, accuracy of diagnosis is difficult in such fevers, but fortunately for the patient and clinician, host immunity as a rule is quickly established and recovery promptly occurs.

The fevers of long duration are tuberculosis, certain forms of sepsis, typhoid fever, paratyphoid fever, meningitis, acute rheumatic fever, syphilis, leprosy, malaria, malignancy, endocarditis, leucemia, and actinomycosis.

Here I deem it important to call attention to the erroneous conception of the term sepsis, as so frequently alluded to by the clinician. Sepsis always implies a blood stream infection, one in which the injurious agent is multiplying and elaborating its poisons in the circulation. In reality it is a bacteremia. We must bear in mind that the specific injurious agent even in such localized infections as a single furuncle is from time to time accidentally entering the blood stream. As a rule these rather sparse microorganisms are readily destroyed by the normal lytic substances which play such an important part in host defense. Sometimes they are only inhibited from multiplying while in transit through the circulation and lodge in distant parts, there to complete their life cycles and set up further inflammatory changes. Most of the cases of endocarditis are familiar examples of secondary lesions in remote parts, the result of survival of the microorganisms during blood stream transportation.

Malignancy.—Certain neoplastic invasions give rise to a febrile state which lasts over a period of months and for this reason, neoplasms have been classified as causative agents of fevers of long duration. Early in malignancy, it is unusual to have fever. When malignancy *per se* produces temperature, it is the result of the absorption of noxious products from the degenerating neoplastic mass. These products are rarely ever in sufficient quantities or of such high toxic property as to occasion more than a slight elevation of temperature. Furthermore, such temperature rises are intermittent in character for the reason that there is not a continuous discharge and absorption of the products of disintegration. Later, when pyogenic infection occurs in the tumor mass, practically constant temperature is the result.

Leucemia.—The fever existing in the leucemias, both myeloid and lymphoid, is, in the light of our inadequate knowledge of the etiology of such conditions, explained on the same basis as is the fever seen in malignancy; it is assumed there is great destruction of cells with subsequent absorption of disintegrated products.

Tuberculosis.—Of all the fevers of long duration, that caused by tuberculosis is likely to give the physician the most concern, since, so often, the infection is insidious and presents a low grade temperature, intermittent in type. In such a condition, especially where there are no definite physical signs and little or no expectoration, without demonstration of acid fast bacilli, incorrect interpretation of the complex is not uncommon. Here a careful and accurate history and intelligent valualization of the clinical symptoms is of extraordinary suggestiveness, and always of utmost importance in allowing us to arrive at an early diagnosis. This, reinforced by repeated careful physical examinations and such laboratory aids as x ray examinations, complement fixation test, tuberculin reactions, and animal inoculations always render an early accurate diagnosis comparatively simple. Hilal tuberculosis, especially in the young, is a condition very often overlooked because not suspected. Local signs are sometimes absent and when present frequently require manipulative skill for their detection on physical examination. It is here that the technical

skill of the röntgenologist so frequently determines accurately the position and extent of the tuberculous lesions. It has been my experience to observe not infrequently continued fever in children, with incrimination of nasopharyngeal or tonsillar infections, and even pyelitis as the etiology, when careful study would disclose hilal tuberculosis. So also it is important to call attention to renal tuberculosis, a morbid process so frequently overlooked and at times surprisingly difficult to diagnose. Persistent frequent urination without bladder disturbance is always suggestive. Here, discovery of tuberculous lesions elsewhere, such as in testes or prostate or lung; finding tubercle bacilli in the urine; localization of lesions by cystoscopic examination, and in some instances the tuberculin test, are all valuable diagnostic aids.

Septic conditions.—Of the septic conditions that cause fever of long duration it is essential early to determine their etiology and the location of the offending foci. The etiological factor can sometimes be determined through repeated blood cultures and by examination of the body fluids for specific immune bodies. As to the location of the focus responsible for the process, the various cryptic infections occurring in the upper respiratory tract, the alimentary tract or the genitourinary tract, should be carefully considered and all modern methods employed as an aid in arriving at a diagnosis.

Deep seated suppurative foci give considerable trouble at times. Perinephritic collections of pus, retroperitoneal and subphrenic abscesses in my experience are offending foci usually difficult of diagnosis and should always be considered when dealing with continued fever of determined origin.

Endocarditis.—In infectious endocarditis, either socalled malignant (usually gonococcal) or otherwise, it is essential in order to arrive at a diagnosis to locate the source of infection, since in nearly all cases the endocardial lesion is secondary or metastatic. Even in old chronic valvular defects where the acute lesions develop, the excitants have usually been transported from some new and distant focus of infection. In subacute infectious or bacterial endocarditis we have a condition of long duration and one remarkable for its latency. For weeks the patient may be free from signs and symptoms, or the only noticeable symptoms may be the continuous daily rise of temperature, even though slight. If the attack is mild in type, the patient may keep about and even attend to his work. Here blood cultures are frequently negative, but several should be made. As the disease progresses, fever increases and the patient may have chills, sweat, anemia, and painful splenomegaly due to infarcts. The blood shows a leucocytosis and secondary anemia.

Typhoid and paratyphoid.—Typhoid and paratyphoid infections, with their classical pictures and cardinal diagnostic prodromal signs, make many cases remarkably easy of diagnosis. The early recovery of the causative organism from the blood stream or the later demonstration of antibodies in the tissue fluids (Widal reaction), naturally make the diagnosis positive. In the absence of positive laboratory findings such as culture or Widal, and with one or two clinical symptoms present positive affirmation of the existence of one of these enteric infections is not possible, and one should be cautious in such cases in making a diagnosis dependent entirely upon clinical picture and course. It is well to bear in mind that a leucopenia with a relative increase in the number of lymphocytes is usually present in the early stages of typhoid but disappears as a rule upon the full establishment of the intestinal lesions, as then secondary infection complicates the host resistance and response.

Syphilis.—In syphilis, the history of infection, the objective signs such as skin lesions, enlarged glands, mouth and throat lesions (patches, ulcers, perforated hard or soft palate), the demonstration of Treponema pallida in lesions and the Wassermann reaction are always important diagnostic aids. In cases in which the history is negative and objective signs are absent, we must rely practically solely on the laboratory examinations, especially those of the blood and spinal fluid.

Rheumatic fever.—In rheumatic fever, the history of sore throat (tonsillitis, pharyngitis), the sudden onset, the involvement of the large joints in succession, and profuse acid sweats are characteristic. The blood shows a leucocytosis and in some cases the causative agent may be recovered by culture methods.

Malaria.—Malaria is one of the conditions to be eliminated in the face of a long fever either remittent or intermittent. With the clinical picture of rigors and temperature occurring at regular intervals, the acute type of infection either tertian, quartan, or estivoautumnal, can be readily suspected. The chronic form, especially aestivo autumnal, presents greater difficulty, as here the rigors may be entirely absent and the temperature quite atypical. Demonstration of the parasites by means of stained blood films naturally establishes a diagnosis. However, it must be remembered that often in the chronic type the peripheral circulation is free from parasites and resort must be had to splenic puncture in order to secure proper material for diagnosis. Black water fever as a type of malaria, with its usual splenomegaly, generally presents no difficulty at diagnosis, although its successful treatment is usually difficult.

Noninfectious fevers.—Noninfectious fevers are those that, as far as we know, are not produced by living injurious agents or their poisons. They are caused by such products as inorganic and organic (nonmicroorganismal) poisons. Brain injuries, cerebral hemorrhage, burns, Graves's disease, are such examples. In all of these, fever is produced by little understood foreign substances that may be regarded as autointoxicant.

CONCLUSIONS

In conclusion, I want to call attention to the fact that the determination of the etiology of long fevers produced by microorganisms and their poisons is often of paramount importance from the viewpoint of possible chemotherapy, serotherapy, and vaccinotherapy; for example, in streptococcus septicemia, vaccines or antitoxins are indicated (vaccines and serotherapy). In malaria, the detection of the parasite in the circulation calls for the administration of quinine (chemotherapy); in meningococcal meningitis, the determination of the cause permits the prompt administration of antitoxin (serotherapy).

Some Clinical and Pathological Findings in Disorders of the Rheumatic Group*

VINCENT COATES, M.A., M.D. (Cantab.), M.R.C.P. (Lond.)
Bath, England

The well known researches of Poynton and Payne are the foundation of the bacterial theory of rheumatic fever and there is now a growing conviction among pathologists that streptococci of low grade virulence akin to those found normally in the alimentary tract are the organisms responsible. What has been understood as conflicting evidence and vitiating the findings of Poynton and Payne is the fact that many observers have failed to find the Diplococcus rheumaticus, while some experimenters have been able to repeat the performance of Horder in producing lesions similar to those found in man by animal inoculation of streptococcus faecalis.

Costa and Irish, however, have cultivated diplostreptococci from subcutaneous rheumatic nodes, while no observer has succeeded in demonstrating experimentally that organisms other than streptococci can produce the type of lesion so well illustrated by the periendomyocardial subcutaneous and joint synovial lesions, characteristic of rheumatic fever. On the other hand Carey Coombs (1) in his Long Fox lecture and again with Geoffrey Hadfield (2) has pointed out that the essential difficulty in reproducing in animals cardiac lesions faithfully mimicking those of man, lies in the fact that experimentally, organisms are introduced into the circulation and therefore into the heart in a different manner to that which obtains in human rheumatic infection.

FIG. 1.—Rheumatic fever. Valvular endocardium. Section of "vegetation" of acute rheumatic endocarditis. A nodule of inflammatory cells lies beneath the valvular endocardium. Its histological characters are essentially those of the nodule found in the myocardium and mural endocardium. At one point the stretched endothelial lining has ruptured and a protective mass of fibrin lies over the rupture.

A further important consideration is the impossibility in animals of exactly reproducing conditions of heredity, environment and other factors predisposing towards the lowering of immunity, which conspire in man to make him susceptible to organisms reverting from saphrophytic citizenship to the rôle of profiteer: otherwise every breach of the alimentary mucous membrane would result in not only penetration of a jumping off party of streptococci, but consolidation of these. It is in experimental animals as in man a history of many offensives, but few objectives gained. Neither in man nor in animals is it possible to estimate the bogey for the course.

Poynton and Payne, Poynton and Still, Aschoff and Carey Coombs have been able over the course of time to show that the tissue reaction occurring in rheumatic fever is constant, that is to say that the pathological pattern is absolute whether the lesions occur in the heart joints or subcutaneous tissues. The essential pathological features are to quote Carey Coombs (1) "those of a proliferative reaction characterized especially by the formation of giant cells with a mild leucocytosis on a background of fibrin. Foci of this kind are found not only in the myocardium but also in the rheumatic valve, pericardium and joint while the subcutaneous node so characteristic of rheumatic infection is only the submiliary nodule writ large."

Regarding rheumatic fever as a de luxe edition of the smouldering rheumatic infection of childhood, and arguing on analogy, it was thought likely that in the same way that the cardiac vegetations had subcutaneous homologues, so might the submiliary nodules also be represented. And in point of fact these have been found (3); small gritty granules barely discernible from the normal, which represents a subpalpable phase of the infection. These occur at sites exposed to friction and are most easily palpated along the ulnar borders and over the vertebral spines. The accompanying photomicrographs of such a nodule in a case suggesting rheumatic infection but as yet without other physical signs shows the same tissue reaction as that which occurs in well established rheumatic lesions.

An investigation with Dr. R. E. Thomas (4) yielded the fact that a large number of children who give the history of growing pains, stiff necks, sore throats, etc., have such nodules which indicate that the barriers of immunity are being assailed with minor success; for we can conceive rheumatic fever as the complete breakdown of the defense mechanism used against the invasion of alimentary streptococci whenever immunity is lowered, either by virtue of heredity or by the correct assembly of factors as yet improperly understood—pieces in a jigsaw puzzle as it were—stress, damp, lack of sunlight, failure of the iodine metabolism, etc.—somewhat like the rhachitic mosaic, calcium phosphorus imbalance, deficiency of vitamine and the domestic complex; whereas a smouldering infection is a partial dislocation of such a service.

Turning now to the question of arthritis of the rheumatoid variety one is impressed on reviewing certain types in a large series of cases by the frequent history obtained either of rheumatic fever or "hav-

Fig. 2B

Fig. 2-a, and Fig. 2-b.—Rheumatic fever, Subcutaneus node. Sections of a relatively large lesion arising during the acute stage of the disease in a child. The lesion is in a fairly early phase. A mass of autolysing fibrin occupies the centre, (C) The intermediate zone is composed of inflammatory cells. (I) The peripheral zone, of granulation tissue in which at a later stage large numbers of young capillarics arise (P).

ing just escaped rheumatic fever," which is in accord with the findings of those observers (5) who make the percentage of cardiac lesions occurring in such cases round about the region of twenty: and by an antecedent history of physiological or pathological stress, damp and so on, comparable to conditions proved to exist in the case of the rheumatic child. Moreover, in addition to the occasional occurrence of large subcutaneous nodules clinically comparable to the classical nodule of rheumatic fever, the millet seed granules already referred to as occurring in rheumatic children can be found with comparative frequency at the same sites as in the latter and also about the joints. In a paper (at press) with Dr. Carey Coombs on subcutaneous nodules sections are shown of nodules removed from cases of arthritis of the rheumatoid type including Still's disease.

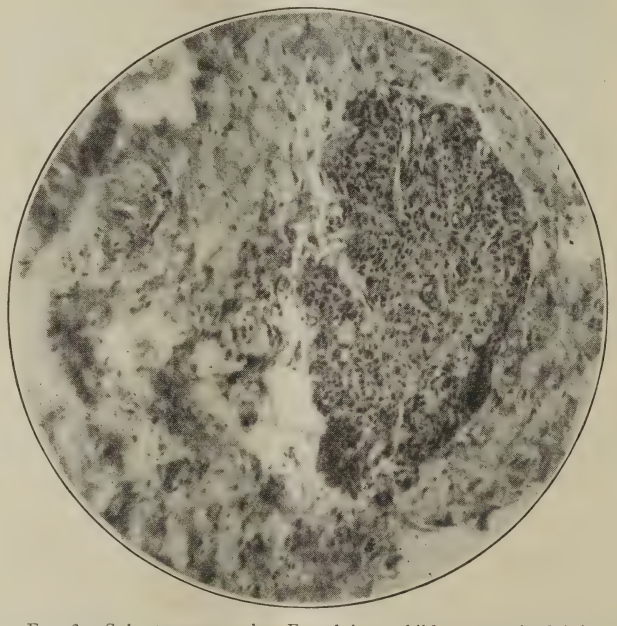

Fig. 3.—Subcutaneous node. Found in a child suspected of being rheumatic but who was afebrile and had no signs of organic cardiac disease. The lesion, only just palpable, has, in miniature, all the characters of the larger lesions found during the acute phase of frank rheumatic infection. It is sharply circumscribed and rich in newly formed capillaries.

The following are clinical notes of two cases, rheumatoid arthritis and Still's disease with photomicrographs of sections of large subcutaneous nodules removed from each:

Case I.—An unmarried woman of thirty-six. Onset of arthritis insidious, five years ago. History of scarlet fever in childhood. First seen three years ago when Ewald's test meal showed achlorhydria. Relapse two years ago. Fusiform joints, enlarged spleen and glands, relative and absolute lymphocytosis with secondary anemia. Absolute achlorhydria by fractional test method. Irregular pyrexia with a clinically undamaged heart but large subcutaneous nodules.

Case II.—A school girl of thirteen. Six months' insidious onset of arthritis. History of growing pains, etc., but no rheumatic fever or chorea. Bronchitis with some root and generalized fibrosis. Fusiform joints, enlarged spleen and glands, relative lymphocytosis and secondary anemia. Irregular pyrexia and an enlarged heart without valvular leakage. Large subcutaneous and millet seed nodules.

Pathologically, therefore, following a clinical lead we are forced to the conclusion that the lesions both of rheumatic fever and the smouldering rheumatic infection of childhood, and certain forms of rheumatoid arthritis are produced by an infection, giving rise to an identical tissue reaction.

The only tissue reactions which bear a superficial resemblance to those described above are found in

gout and syphilis. Sodium biurate crystals in frozen sections eliminate the former, while universal specific endarteritis and periarteritis are distinctive enough to eliminate the latter.

From the clinical viewpoint is this feasible? It would appear to be so. It is notorious that the clinical manifestations of many specific infections are protean and ubiquitous. Compare the different sites of attack by the Spirocheta pallida: neuropathic (selective at that) visceral, cardiovasculorenal, joint

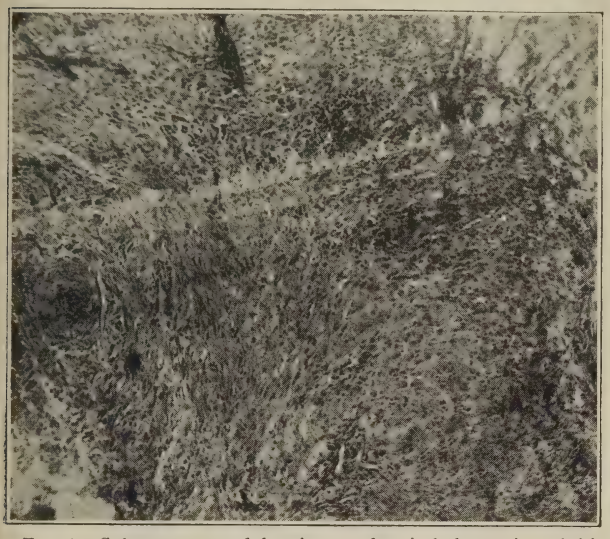

FIG. 4.—Subcutaneous nodule. A case of typical rheumatic arthritis with enlarged spleen and glands and achlorhydria. A central mass of necrotic tissue which has become hyaline, surrounded by a fibrocellular zone.

and bone. If therefore certain individuals have certain susceptibilities in respect of vulnerable spots in one disease, it is not unreasonable to suppose that this holds good for other diseases. That the reaction is more exuberant in one than in another individual is in keeping with the syphilitic simile.

Of what value then is a constant tissue reaction in the diagnosis of this type of infection?

In the large majority of infections produced by a known microorganism the tissue changes are constant and specific. The histological features of tuberculous infection are established as a routine method of diagnosis, and similar clear cut specific histological pictures accompany such diverse infections as amoebic ulceration of the bowel and gonococcal salpingitis.

In the present state of knowledge we are still without any reliable evidence that streptococcal infection gives rise to the formation of antibodies which can be used to demonstrate in a truly specific manner any known immunity reaction; and we are driven to the study of tissue response and histological criteria in the diagnosis of these infections, as it is now the custom of election to use this method in extra pulmonary tuberculosis.

SUMMARY

The bacterial theory of rheumatic fever has been briefly touched upon. The chief points in favor of an alimentary streptococcal infection appear to be the specificity of the tissue reaction irrespective of the site affected, in man: the occasional mimicry of similar lesions produced by experimental inoculation of streptococci, in animals: and the absence of such lesions as the result of other infections in both man and animals.

Be this as it may, sections of millet seed nodules in rheumatic children as yet without clinically demonstrable cardiac lesions, sections of large subcutaneous nodules in rheumatoid arthritis and Still's disease, have been shown to illustrate the same pathological pattern as that which is characteristic of rheumatic fever, with the obvious inference that the virus is a common one.

In addition the finding of millet seed subcutaneous nodules and a similar history of stress, damp, or lack of sunlight, known to exist in rheumatic children, with the not infrequent history of rheumatic fever in certain types of rheumatoid arthritis, suggests a clinical link between these conditions.

I wish to thank Dr. Carey Coombs, physician to the Bristol General Hospital, for allowing me to use the pathological material contained in the first part of this paper and for his permission to express in part some mutual work on rheumatic nodules.

My special thanks are due to Dr. Geoffrey Hadfield, pathologist to the Bristol General Hospital, not only for sectioning and microphotographing morbid material and for his skilled reports without which it would have been impossible to proceed but also for his valued criticism and advice.

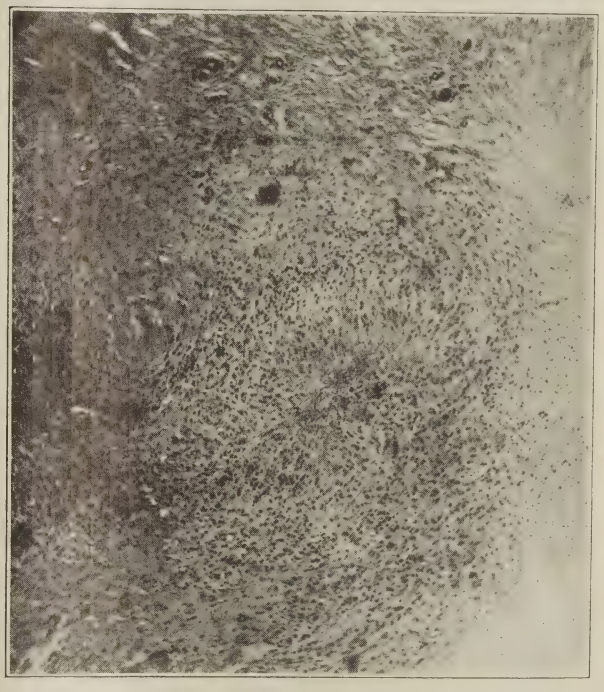

FIG. 5.—Still's disease. Subcutaneous nodule from a typical case showing fusiform joints with enlarged glands and spleen. Central necrosis with peripheral fibroblastic reaction as in the subacute phase of frank rheumatic infection.

The Possibilities of Error When Diagnoses Are Based Solely Upon Anamnestic Records*

HENRY J. JOHN, M.D.

Cleveland, Ohio

A subjective history of the patient and his ailments is a very essential factor in making a diagnosis but the objective evidence is infinitely more important. This fact, and the danger of overlooking the symptoms of one disease, particularly if they are overshadowed by those of another, are clearly brought out by the following two cases:

Case I (167,725).—A young girl, eighteen years of age, came to the Clinic June 3, 1926, complaining of drowsiness, excessive appetite, polydipsia, polyuria with nocturia, and pruritus vulvæ. These symptoms were of two months' duration and, since they simulated so closely the usual symptoms of diabetes, she and her friends had become convinced that she had this disease and she had therefore sought medical advice.

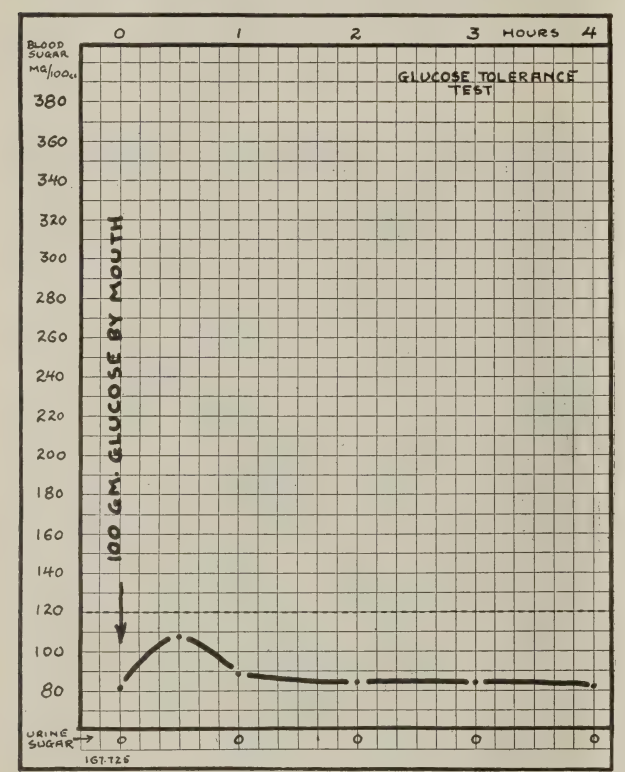

Fig. 1.—Chart I. (Case I.). Result of glucose tolerance test made in the case of a patient who complained of polyuria, polydipsia, nocturia and pruritus vulvæ. Note the supernormal carbohydrate tolerance. This test ruled out the diagnosis of diabetes in spite of the presence of typical symptoms of the disease. If the test had not been made diabetes would doubtless have been the diagnosis.

Physical examination revealed a well developed and well nourished young woman, five feet six inches in height, weighing 118 pounds, with a pulse of 60 and blood pressure of 110/70. Physical examination revealed nothing of importance. The red blood count was 4,470,000, white count 7,300, hemoglobin eighty per cent. A blood sugar examination made on the same day showed a blood sugar value of 82 mg. per 100 c. c.; the blood Wassermann test was negative; urine examinations made on two successive days showed no sugar, a faint trace of albumin in the first examination, but none in the second. On June 7th a glucose tolerance test was made. During the test the water intake was 850 c. c., the urine output 490 c. c.; plasma chlorides 585, blood urea 15, blood uric acid 1.7, blood creatinin 1.1 and nonprotein nitrogen 50.4 mg. per 100 c. c. The results of the test, as shown in Chart I, indicate clearly that the patient did not have diabetes—in fact her carbohydrate tolerance was above normal.

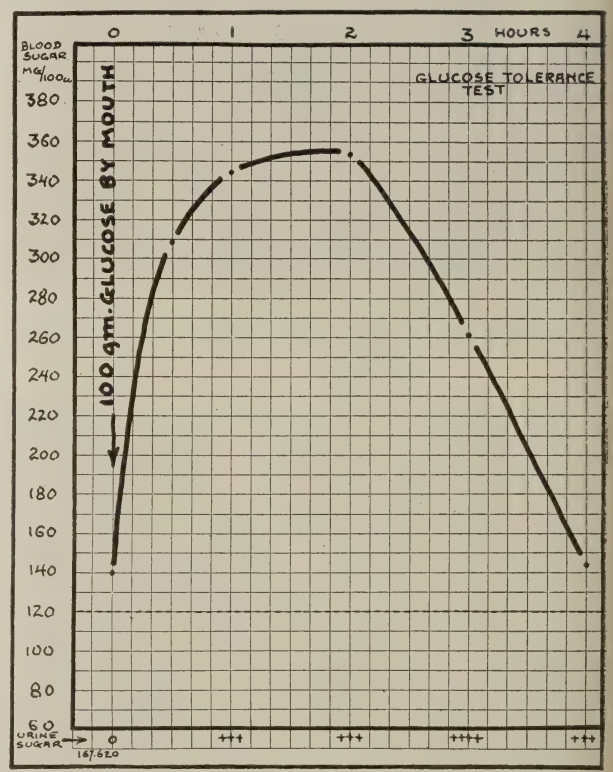

Fig. 2.—Chart II. (Case II.) Result of glucose tolerance test made in the case of a patient who had a severe case of hyperthyroidism (B.M.R. +82). Glycosuria was present but the postprandial hyperglycemia was very slight (134 mg. per 100 cc.). Note the very low carbohydrate tolerance. This test betrayed a diabetic condition which would have been overlooked if the test had not been made.

Case II (167,620).—A woman fifty-eight years of age. She came to the Clinic because she had a goitre and because she was suffering from nervousness, palpitation of the heart, loss of weight (thirty-three pounds in six months), hyperhidrosis—all of these being typical signs of toxic goitre. She had noticed a fullness in the throat for four or five years; the other symptoms had been present from six to eight months. For six months she had been practically bedfast.

Physical examination revealed a thin, tall woman,

*From Cleveland Clinic.

weighing 115 pounds, which was thirty-three per cent. less than her normal weight. Her temperature was 99, pulse 140, blood pressure 209/100.

There was a bilateral, firm, diffuse, irregular enlargement of the thyroid gland. The chest was clear, the heart was not enlarged, there were no thrills or murmurs. An examination of the abdomen and pelvis revealed nothing of importance except for a prolapse of the rectum with hemorrhoids.

The urine examination showed a heavy glycosuria, a faint trace of albumin, no acetone. The blood sugar was 134 mg. per 100 c. c., four hours after a meal. The blood Wassermann was negative.

A blood sugar content of 134 mg. per 100 c. c. four hours after a meal would hardly catch anyone's attention, as such a figure is so close to the normal that one would be apt to disregard it; however, the fact that glycosuria was also present led us to make a further investigation and a glucose tolerance test was performed on June 8th, the results of which are represented in Chart II. During the test the water intake was 850 c. c., the urine output 270 c. c.; the sugar intake was 100 gm., the sugar output 4.06 gm.; plasma chlorides 585, blood urea 39, blood uric acid 1.4, blood creatinin 1.0, and nonprotein nitrogen 42 mg. per 100 c. c. The test showed definitely that a diabetic condition was present, although the patient had no diabetic symptoms. Because of the severe hyperthyroidism—she had a basal metabolic rate of plus 82 per cent.—the diabetic condition might have been entirely overlooked if the glucose tolerance test had not been made.

DISCUSSION

In these two cases we have a striking contrast. In the first there was a history of typical diabetic symptoms in the presence of a nondiabetic condition; in the second case there was no history of diabetic symptoms, although a definitely diabetic condition was present.

These cases show clearly how misleading a history of the patient's symptoms may be and how easily a mistaken diagnosis might be made or a serious complication overlooked, were we to base our final judgment on this history and not obtain sufficient objective evidence of the true status of the patient. Even glycosuria in the presence of hyperthyroidism is not considered very abnormal, in fact it is generally considered to be a fairly common accompaniment of the condition. It is impossible to tell how many cases of diabetes have been missed for this reason, as no one has followed up such a group of cases systematically, in order either to confirm or definitely to rule out a diabetic condition. In the milder cases, those in which the disease has caused only an impairment of the carbohydrate tolerance, the symptoms doubtless clear up after thyroidectomy. In some of the more severe cases, however, diabetes probably develops later in life, but the fact that it was initiated during the attack of hyperthyroidism is doubtless not recognized. In order to avoid this danger it is imperative never to disregard the presence of glycosuria in a case of hyperthyroidism, even if there is but a moderate degree of hyperglycemia.

Gastrointestinal Diverticula*

WILLIAM SEAMAN BAINBRIDGE, Sc.D., M.D., C.M.
New York

(*Concluded from page 323*)

Case XI.—A. G.; female; fifty-four years of age; married. This patient consulted me August, 1922, following a laparotomy which had been performed by a surgeon in another city four months earlier. This surgeon had pronounced the condition found ("a tumor of the upper rectum as large as an orange") as irremovable, and had simply closed the wound.

After thorough examination I decided that the condition more closely resembled that of diverticulitis, or of an abscess, than carcinoma. Medical care was instituted and the patient advised to postpone operative procedure. Gradually she began to improve and by December, 1922, had gained five pounds.

January, 1923, I was called in consultation by her physician who reported that the mass in the left pelvis was as large as an orange and the patient had a temperature. I diagnosed the condition a pelvic abscess and advised operation. The following day the patient ruptured the abscess into the bladder, and passed seven or eight ounces of pus. Following this irrigations were instituted, and at the end of a month the patient was convalescent and the mass had practically disappeared. However, many of the intestinal symptoms were still evident and exploratory laparotomy was advised.

April, 1923, on opening the abdomen, the great omentum was found to be adherent to the abdominal wall. The great omentum and the transverse colon were adherent to the uterus, anteriorly, and to the left broad ligament and to the bladder. These were carefully separated, and a hole was found in the bladder, about the size of the end of the index finger. This was turned in with interrupted stitches. From the opening into the bladder there was a tract extending in a circuitous way to the pelvic colon at the site of which appeared to be the remains of a diverticulum. Evidently a pelvic abscess had formed from a diverticulum of the sigmoid and discharged into the bladder.

The lower part of the small bowel was adherent and markedly fixed in position, and twisted by adhesions between it and the fundus. The appendix which was twisted was removed in the usual way. There were other small diverticula along the sigmoid. These, however, were not causing trouble and did not require surgical treatment.

The patient had a rather stormy convalescence, due

*Read before State Medical Association of Texas, May 26, 1926.

to her badly run down condition, but in October, 1924, she wrote that she was in fine health. A more recent letter, April, 1926, indicates that the patient is leading an active and normal life and that the corrective surgery of the intestinal tract has entirely eliminated the socalled irremovable carcinoma. There has been a gain of forty-five pounds in weight since the operation.

Case XII.—P. T.; female; fifty-five years of age; married. Five years previous to consulting me this patient had had severe spasms of pain across the abdomen, after every meal, and on one occasion had vomited bright red blood after eating. Her condition grew worse gradually until she was unable to take any solid food, and her weight fell from 175 to 137 pounds.

The patient did not improve under medical treatment and finally it was decided to resort to operation.

Laparotomy was performed April 16, 1926. The "last kink" was markedly developed. In spite of a thorough clearing out with oil and colonic irrigations for days previous to operation, there were scybalous masses of feces in the loop of the pelvic colon. None of these masses was below this loop of the gut. A pericolic sigmoid band was cut transversely and sewed longitudinally. The appendix contained enteroliths, and was removed.

There was a band attached to the fold of Treves[1] which twisted the entrance of the ileum into the large gut, when the patient was in an upright posture. This band was corrected and the fold of Treves freed. There was a large, diverticulated, mobile cecum. This was treated with iodine; plicated and fastened to the right posterolateral shelf at the level of the lower pole of the right kidney. A number of bands along the ascending colon (Nature's ineffectual effort to hold the gut in place) tended to constrict the bowel; these bands were bisected and the raw surfaces were allowed to remain in the pocket thus made in the right flank along the ascending colon (a modified method of Waugh of London). The gallbladder was surrounded by adhesions and adherent to the duodenum and the gastrocoloc omentum. The gut was detached from the gallbladder and the raw surfaces of the gallbladder covered. There was a small diverticulum at the apex of the gallbladder where, by traction, the bowel had elongated the tip, the rest of the organ being held in position by adhesions.

The pylorus was somewhat narrowed and a posterior gastroenterostomy was performed with an opening large enough to admit four fingers. There was a distinct scar and an indentation of the posterior superior aspect of the first portion of the duodenum. This was carefully outlined and a pursestring stitch of linen was placed around an area on the anterior wall just above the posterior ulcer. A red hot cautery was used to go through the anterior wall and into the ulcer; a finger was held under the ulcer as the cautery was used to prevent perforation of the under surface of the gut. The pursestring was tied and reinforced. The diverticulum of the gallbladder was enfolded.

[1]George F. Chandler, as a routine measure in all cases of appendicitis which are not gangrenous, places an artery clamp on the ileal side and another on the caecal side, and with a pair of scissors cuts right through to the junction of the ileum with the caecum, thus freeing the fold of Treves and removing the interference with the proper function of the valve.

The above case is too recent to permit of postoperative deductions. It is reported, 1, because of the unusual site of the diverticulum (gallbladder); and 2, to emphasize the importance of differential diagnosis in cases where, because of extensive pathology of the intestine, malignancy might be readily suspected.

Briefly summarizing what we know today of intestinal diverticula, it is evident that while some are congenital, a far greater proportion are acquired. While the etiology of diverticula is obscure, the acquired type may, frequently, be traced to a traumatism, an inflammation (sometimes a combination of these two); or to a persistent excessive distention (evolutionary type) of the gut, due to retarded drainage. In the latter case a continuous abnormal strain is placed upon a (possibly weakened) point in the intestinal wall until, eventually, evolutionary changes take place. Accumulation of hardened feces is greatest in the sigmoid where diverticula are frequently found, and a point which Lynch and Felsen report "is a site so favorable for the development of carcinomatous tumors."

From the therapeutic viewpoint, intestinal diverticula may be divided, roughly, into three main groups:

1. There are the small multiple diverticula which evidence no symptoms. These are of little importance in the scheme of things, and usually may be disregarded.

2. There are the acute types of diverticula—with abscess formation; with diverticulitis; or with degenerative, possibly malignant, change. These may be recognized and must be treated surgically.

3. Most important are the considerable group of diverticula which constitute the main factors in many pathological conditions—conditions where the effect is not well correlated with the essential cause. These intestinal diverticula of the colon are selective points for the retention and absorption of toxins from putrefactive bowel content and as such are, doubtless, often the underlying but unrecognized causative factor in many remote toxic symptoms—abnormal heart, thyroid and mammary conditions, premature senility of the organs and certain psychoses. When all likely sources of infection (teeth, tonsils, gallbladder, etc.) are being considered, the possibility of the foci occurring in these pockets—diverticula—of the gastrointestinal canal should be thoroughly weighed. Unless all possible infective sites of the gastrointestinal tract are investigated as a routine measure, wherever there is an unidentified evidence of toxemia, the patient may be dead long ere the local toxic area is defined and eliminated.

Careful clinical and laboratory observation will usually demonstrate gastrointestinal diverticula. In this connection may I add a word concerning the clinical examination of the patient with gastrointestinal symptoms? Often such a patient, whose intestines have been thoroughly cleaned out by purgatives and irrigations and are, as a result, flaccid and flabby, is placed on the examining table in a prone position. It is due to this method of examination that many mechanical defects of the intestines escape the diagnostician. These patients should be examined in an upright posture in which case the viscera will be in their natural positions and relation to each other. Often placing the patient in a modified Trendelen-

burg position during examination will reveal conditions demanding attention.

In beginning diverticula—before the resilience of the gut has been permanently impaired—therapeutic measures sometimes prove beneficial. A properly fitted belt may correct the tendency of the viscera to downward displacement, lessen the angulations and, eventually perhaps, strengthen the abdominal supports, with final mechanical readjustment of the organs. Paraffin oil (to keep the feces soft); biweekly doses of barium or bismuth, one ounce in emulsion or buttermilk, and, where there is spasm of the colon, luminal may prove useful measures.

Cases of intestinal diverticula with symptoms practically always require surgery—the amount to be determined by individual need. There is a wide range of opinion regarding the type of surgical procedure required. Roberts and Drueck believe that diverticula (of inflammatory type) may be relieved by medical measures. Lynch states "that the treatment of diverticulitis should be conservative" and adds "that when acute abscess occurs, the same treatment applies as in any other part of the abdominal cavity." Erdmann believes "that the acute types (diverticulitis) call for drainage, or excision and suture as does appendicitis." Mayo (W. J.) states "that if a considerable size tumor is present and the symptoms do not show a tendency to disappear, it is better to make a primary resection of the bowel before abscess and fistula supervene to render the patient a prolonged invalid." Where diverticulitis is a factor, Kelly isolates the diverticulum; ligates the mesentery, if present, and the diverticulum, "keeping the bowel wall well elevated, and pinched together to prevent any escape of the contents."

In my experience I have found that these diverticula of chronic type are of great importance. They may be eliminated, in many instances, by such simple surgical measures as cutting bands; straightening kinks; and enfolding the diverticulum. By freeing angulations, fusions, etc., and thus lessening backward pressure, resistance to normal onflow of the intestinal content is diminished and the static condition relieved. Extreme cases may call for colectomy or short circuiting—a procedure described in several of my earlier papers, or such methods as Patterson's "colonic exclusion"—or any equally good substitute. Diverticula may follow surgical procedure on the intestinal tract at a site weakened by the removal of natural supports. After the excision of the appendix, all longitudinal bands should be anchored, and in all gastrointestinal surgery impaired areas should be reinforced to prevent subsequent diverticulations of the intestine.

"A pronounced diverticulum is a troublesome structure; liable to acute inflammation (diverticulitis); with symptoms and results as dangerous as acute appendicitis. Diverticula which once have been the seat of diffuse inflammation may readily be excited to subsequent attacks, with resultant ulceration; perforation or even complete obstruction of the gut." Possible malignant degeneration at the site of the diverticulation is always a factor to be considered. Prompt surgery in symptomatic diverticula must be, of necessity, the method of choice.

34 Gramercy Park.

The Endocrine Glands of Rats in Parabiosis*

PROF. GIACOMO PIGHINI, M.D.
and MARIO DE PAOLI, M.D.
St. Maurizio, Italy

(*Continued from page* 358)

All these modifications are accompanied by the liberation into the canaliculi of lipoid products derived from degeneration of the spermatic cells. Figs. 14 and 15 reproduce some of these tubules, treated with Flemming, from the fifth and sixth pairs, corresponding with those in Figs. 11 and 12. In this tissue is seen in the first place an increase of Leydig's cells, albeit with the interstices filled with lipoid material in a very advanced phase; secondly, complete atrophy of the testicles has taken place, so that the interstitial tissue appears atrophic and devoid of lipoid and anisotrope substances.

As already remarked, this type of changes in the spermatic course of development may be confined to certain groups scattered along the canaliculi, or may extend throughout the entire gland; and in the latter instance, as in states of very prolonged parabiosis, the gland becomes atrophic, falling from two grams or more of weight to a few tens of centigrams.

*From the Lazzaro Spallanzani Scientific Laboratory of the Reggio Emilia Psychiatric Institute, directed by Prof. G. Pighini.

The ovary exhibits a very varied behavior in the condition of parabiosis, depending on the age of the animal, its period of sexual maturity, and the general effects parabiosis has had on it. Individual variations are extreme and, when occurring, less reaction is manifested in females joined when very young. Nevertheless even in them, when the condition is long continued, notable modifications occur, which terminate in atrophy of the gland. In the female of the seventh pair, for example, operated on at a month and a half of age and killed four months later at the age of five and a half months, we found distinct alterations (Fig. 16): many ovules in all phases were apparently normal, nevertheless in some were found degenerated masses among the cellular elements of the granulosa. The vessels were greatly dilated, forming veritable lakes of blood. The corpora lutea, well developed in size, presented an enormous dilatation of their capillary vessels, with accumulations of blood in the centre and scarcity of lutein cells, especially toward the centre (perceptible in the microphoto-

tograph). In this pair the ovaries had become well developed and begun in the secondary period to degenerate in respect of their principal structures, the ovules and corpora lutea.

In more mature animals the changes become manifest very early and seem to follow the same process. For example, in the fifth pair, killed in apparent health on the thirty-first day at nine months of age, we observed the same phenomena in the ovary, with great dilatation of the corpora lutea at the centre and with infiltration of plasma cells among the lutein cells, which had become greatly enlarged (Figs. 17 and 17b).

The abnormal presence of plasma cells in small corpora lutea indicates a process going on of trophic alteration in this tissue. In other females, which have decidedly resented the new condition, the involutive process is still more rapid and accentuated. In the second pair, for instance, five months of age, already on the twelfth day after operation the ovary appeared atrophic, the corpora lutea had almost disappeared, and the lutein cells were indistinguishable from the interstitial, while the granular membrane of the follicles showed intense lipoid degeneration (Fig. 18).

Of the eighth pair, united at the eighth month of life, the female died seventeen days later in a cachectic state, atrophy of the ovary being then very pronounced (Fig. 19). The corpora lutea were rare, and in an abundant connective tissue stroma there appeared only an occasional isolated lutein cell, in some instances infiltrated with hematin pigment, atresic ovules in great number, and patches of lipoid matter (with Ciaccio). Rarely was there a mature follicle with some cells of the granular layer in the lipoid infiltration. The vessels were much dilated and overflowing with blood. This picture, of which Fig. 19 conveys an inadequate idea, is indicative of advanced degeneration and atrophy on the part of the gland. As may be seen, the variations are chiefly individual ones, but constitute a progressive series from the first stage of congestion and rarefaction of the lutein cells in the corpus luteum up to atresia of the corpora lutea and follicles and to atrophy of the gland. The theca lutein cells of the granular portion of the follicles, which are undergoing degeneration, at once render the glandular interstitial tissue hypertrophic, so that it appears much more abundant in lipoids; atrophy of the germinative cells of the gland (follicles and corpora lutea) is added, and the interstitial tissue as well becomes atrophic.

When the ovary is greatly degenerated the uterus, too, shows trophic changes in its muscular structure, especially in the internal layer, and increase of connective tissue. The other glands and organs likewise exhibit characteristic alterations, always in proportion to the more or less pronounced reaction of the parabiotic pair to the new condition. The brain is but little affected, merely presenting in case of those dying first in a pair an intense vascular injection. Only in cases where the death of both animals took place soon after the operation and after a violent convulsive crisis was marked congestion observed and production of a considerable increase in the nerve cells. The pituitary gland always showed intense hyperemia in its anterior lobe with dilated capillaries and surplus of blood (for example, Fig. 20 from the eighth pair); and in those cases where decided alterations have taken place in the sex glands the prevalence is observed of basophile cells, small and large. These latter are characterized by small sized nuclei and by excessive development of protoplasm, as though swollen, and stain faintly with the basic stains. We met them in the male of the seventh pair, killed after 165 days, which did not present any notable alterations in the testicles.

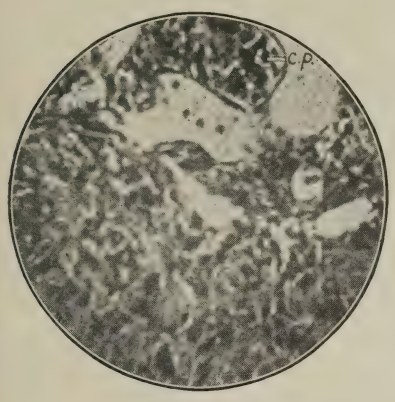
The thyroid appears to function well during the first period, sometimes being hypertrophic with large follicles full of colloid. In atresic animals, however, and those which showed marked alterations in the thymus and sex glands they are found atrophic, with very small tubes containing no colloid but full of cellular detritus from the desquamation of their epithelial walls. Particularly worthy of note were the parenchymatous hypertrophy and the follicular degeneration encountered in two cases of homosexual parabiosis between male and male. Fig. 21 shows one of these thyroids from a male of the third pair which died after twenty-two days of parabiosis. The gland was much enlarged, divided into lobes by hypertrophic connective tissue, and on section showed a number of very large follicles filled with basophile and a few acidophile cells. In many of the basophiles the epithelium was exfoliated and thrown out into the lumen among the colloid. Numerous small vesicles had run together to form reservoirs of colloid enclosed by thickened parenchymal tissue, in which active new formation of follicles was going on. In many of the vesicles were extensive extravasations of blood (Fig. 21, ve.). The excessive vascular dilatation presents a type of parenchymatous struma resembling that encountered by one of us (Pighini) in his experimental study of goitre in rats.

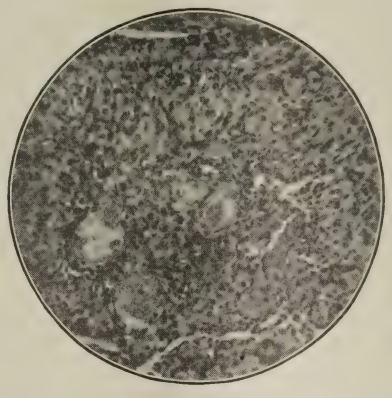
Decided alterations were always met with in the adrenal capsules. The cortex showed marked impoverishment of lipoid substances, which took on with Nile blue a bluish tint; and with the polarizing microscope they appeared scant in cholesterin bodies. This was common to males and females alike and greatly accentuated in cases (as in the first, second, sixth, and eighth pairs) which exhibited major trophic alterations in other glands, particularly in the thymus and sex glands. The medulla was well preserved, seeming rather at times to be hypertrophic in the matter of chromophile cells, causing it to be somewhat chromicized.

In the spleen considerable hypertrophy occurred in the lypmphatic corpuscles of Malpighi; and in the liver a particularly marked production of new lymph nodes. In the pancreas hypertrophy of the islands of Langerhans was constant and sometimes, as in the fifth pair (killed after thirty-one days) was excessive (Fig. 22).

The observations show that the state of parabiosis in rats of different sex, begun at the age of puberty, is badly borne by both the Siamese companions, provoking morbid reactions in the various internal organs which may lead to the death of one or both partners in a very short time. The syndrome of tonic clonic convulsions which is seen soon after operation, regarding which authors who have previously conducted similar experiments are not agreed, is to us an index of the state of severe intoxication suddenly established between the two parabiosed animals, serving as an irritative stimulus to the central

nervous system. This state soon becomes modified by the rapid development of immunizing processes, and the animals before long resume a condition of apparently normal health, but the reciprocal intoxication continues and manifests itself in one or the other in various ways, according to individual constitution.





FIGS. 17a and 17b.—Photomicrograph of ovary of fifth pair.

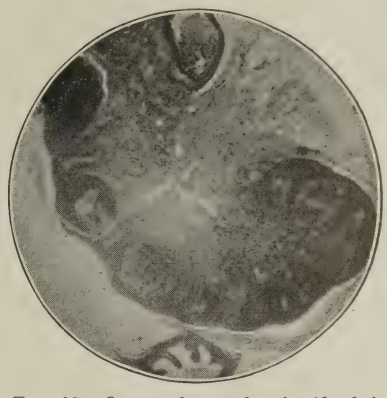


FIG. 18.—Ovary of second pair (fixed in nile blue).

As a general rule, we are able to infer from our experiments only this, the intoxication is least in pairs operated on when very young, during the first two months of life, and in those born of the same litter, but is always greatly accentuated when the two members of a pair are old and of different families. Why the male or the female should be the one first affected cannot be explained unless by resorting to the generic concept of the relative specific qualities inherent in the constitution of every individual.

In homosexual pairs, on the other hand, between two males, with which sex alone we have experimented up to the present time, parabiosis is badly borne, if practised at an age somewhat advanced (seven or eight months), although without pronounced reciprocal morbid reactions in very young animals. Still, in such pairs, as an immediate result of the operation, the identical convulsive phenomenology takes place as in heterosexual pairs, indicating that the reciprocal intoxication is a matter, not of sex, but of differences of humoral exchange existing between individual and individual.

The earliest morbid reactions in this toxic state are seen histologically in the thymus, which sometimes appears altered as early as twenty-four hours after the operation. This tends, as we have seen, to degeneration of the lymphocytic cortical cells and accompanying infiltration of all the epithelial tissue with plasma cells. It is a genuine process of acute intoxication which is set up in the gland with various manifestations (sequestra, etc.), but all tending toward complete lysis.

The presence of plasma cells in the thymus has been observed before in involutive processes in that organ by Ronconi in man and by Solie and Schaffer in various other mammifera. In these last, however, it arises locally by transformation of thymolymphocytes. But such a considerable production as seen in our cases and so rapid we do not think has hitherto been observed in any other condition of the thymus—a fact which shows how greatly this gland resents with promptness and violence the altered humoral condition established in parabiosis. Degeneration of the small round lymphocytic cells is certainly the first step in this process and serves as a chemiotropic appeal to the plasma cells. When these have passed out of the vessels, very probably they continue to multiply locally until they come to constitute the only active cellular element in the connective tissue stroma of the gland. That plasma cells can enter and reproduce themselves in tissues apart from inflammation has already been maintained by Martinotti, Ioannovic, and others. In thymus glands the products of autodestruction of small round cells

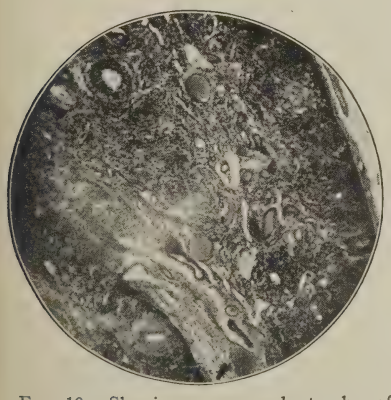

FIG. 19.—Showing pronounced atrophy of ovary of eighth pair at death.

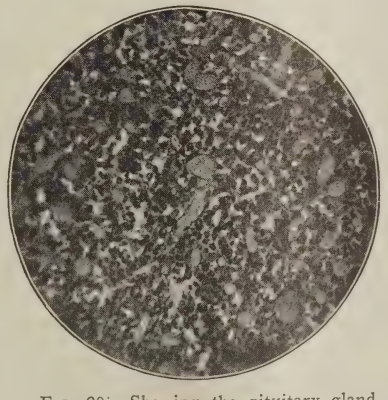

FIG. 20.—Showing the pituitary gland of eighth pair.

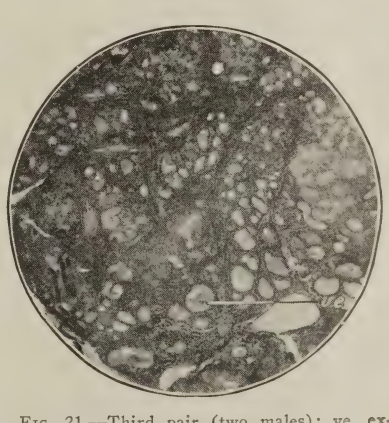

FIG. 21.—Third pair (two males); ve, extravasation of blood into a follicle.

served as a stimulus to the plasma cells and offered them a suitable soil for fermentation and culture, and they so multiplied that the surrounding connective tissue of the gland, in the cases observed, became infiltrated, and the infiltration went so far as to reach the neighboring submaxillary glands (which remained normal so far as concerned their parenchyma cells). Alteration of the thymus was common to all the pairs in parabiosis, as well to those who bore the condition better as to the homosexual; thence arose the immediate reaction to humoral exchange in the two individuals.

This was followed in order of changes by that of the sex glands in heterosexual pairs. The modifications in testicles and ovaries tend to degeneration of the specific inconstant cells of these glands, those of the spermatic vessels and the follicles. We have seen in testicles the early degenerating of spermatocytic nuclei, the fusion of chromosomes, the accumulation of the nuclei of degenerated cells in protoplasmic masses formed in all probability of spermatoblasts, and their disposal by forming rounded masses having the appearance of giant cells, these latter being figures resembling those found occasionally by Ebner in the testicles of rats and regarded by him as products of degeneration. The last stage of this process consists in diminution of the cells of the spermatic series and rarefaction of the canaliculi till nothing is left but the membrana propria and a few Sertoli cells. In the early stages of this seminal degeneration the Leydig cells of the interstitial gland increase in number and size, being loaded with phosphatid and cholesterin lipoid substances (see Figs. 11 and 14). In advanced stages likewise of testicular degeneration and atrophy of the canaliculi the interstitial atrophies also and loses its lipoids. Thus is demonstrated the trophic functional relation existing between the two tissues.

In the ovary rarefaction of lutein cells occurs until the corpora lutea disappear, together with hyperemia and infiltration of plasma cells and atresia of the follicles.

These progressive modifications of the sex glands render animals of opposite sex in parabiosis incapable of impregnating and of being impregnated. But the male of the seventh pair, in full puberal development (at about five months of age) after three months in parabiosis, showed its power of generation with a female placed in the cage of the two partners in parabiosis. The same female, however, after bringing forth and raising her litter of seven, remained in contact with this male for more than a month and continued sterile; and another female continued equally sterile. Killed a little later, this male, as we have seen, showed no evidence of alterations in the seminal canaliculi. Still, a functional alteration existed, which ought possibly to be interpreted provisionally as evidence of a histological alteration.

The females in parabiosis we never succeeded in impregnating with males from without, not even that of the seventh pair, in which the ovaries were shown to be altered.

Concomitant alterations, which however seemed to be produced at a later time when the thymus and sex glands had already been impaired, were found in all the other viscera with individual variations of precocity and intensity. Among these the most constant were encountered in the adrenals and the pituitary gland.

At variance with Matsuyama, who found an increase of lipoid material in the glomerular and fascicular zone of the adrenal cortex, we always found this area in the adrenal glands of both sexes very poor with the polarizer, as well as in phosphatid lipoids, as in anisotrope cholesterin compounds; and this impoverishment we found at the maximum in the pairs most affected by the parabiotic fusion. The medulla was always rich in chromophile cells, but not very rich in chromaffin substances (little chromicized) and very vascular.

In the pituitary there was always very intense hyperemia, and in the majority of instances an evident increase of large basophile cells, resembling those described by Matsuyama under the name of castration cells and pregnancy cells, because found by him predominantly in those states, as well as in parabiosis.

In the thyroid the reactions were evident, were not characteristic, and seemed to be closely associated with individual constitution. We do not know, for the present, how otherwise to interpret the parenchymatous struma found in the dead male of the third pair, a parabiosis of two males. Nevertheless, it seems that in severe cases the thyroid may suffer from a degenerative process affecting its follicles, with narrowing of their lumen, diminution of colloid, and exfoliation of the lining epithelium.

There is considerable hypertrophy also of the islands of Langerhans in the pancreas, and enlargement of the Malpighian lymphatic bodies in the spleen and the lymph nodes of the liver, changes which are especially evident in severe cases. The terminal appearances in the spleen and liver are reported as observed by Pentimalli in protein intoxication in his animals, and must be an effect of the mutual heteroprotein intoxication of two individuals whose circulation is fused into one. The hypertrophy of the islets of Langerhans is not easy of interpretation. The animals joined together have seemed greatly emaciated; their muscular masses have undergone a dystrophic process, while their internal processes of metabolism are modified by the new conditions of reciprocal exchange. It is to be supposed that the organism, under these conditions, would accomplish a change in such a way as to meet the altered metabolism of carbohydrates, among which the principal substances are the sugars. Probably, therefore, a demand is made on the islets of Langerhans for increased effort in their function of regulating this metabolism of carbohydrates and fixing the hepatic glycogen.

Pende has brought fairly out in his treatise the functional synergy of the pancreatic hormones, and especially the insular hormone, with those of the genital organs, and has advanced the opinion that the thymus is associated with them. One of us (Pighini) has found in the pancreas of his thymectomized animals degenerative lesions of the acinous cells, while the islands, on the other hand, seemed always well preserved and even hypertrophic: this accords with Pende's view. The finding now in our parabiosed animals of lesions in the genital glands and the thymus, on one hand, and of hypertrophic islands of Langerhans, on the other, confirms the conception

of functional vicariousness between these glands in regulating glycemia and glycosuria.

Such an anatomicopathological picture requires a number of explanations. First of all, among the authors who have occupied themselves with the subject are some who have not found the details as described by us, or who deny them. Next, it is well to keep before us the method of operation followed in parabiosis. Celostomy, followed also by Matsuyama in his parabioses, has given here a very high percentage of deaths, besides the danger of spreading irritative processes and that of adhesions for the viscera studied in the abdominal cavity, without offering any greater advantage in humoral exchange between the two partners. For these reasons we gave the preference to musculocutaneous ligation over an ample area with scarification of the muscle, as Heyde had already done, thus securing a minimum of lethal results and a sufficient and permanent humoral exchange, as was demonstrated by the rapid elimination of iodine by the kidney of the twin not injected, by the clinical reactions effected immediately and later, and by the anatomical results.

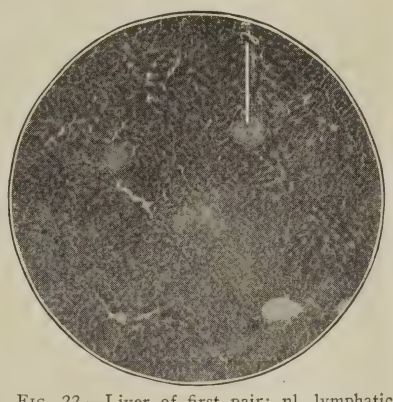

Fig. 22.—Liver of first pair; nl, lymphatic nodule.

Contrary to the opinion of many authors (Schmidt, Matsuyama), we do not believe that musculocutaneous fusion over a wide surface provides better than does celostomy for humoral (lymphatic and sanguineous) exchange between the two partners. This is certain, that by this method we obtained quick reciprocal reactions and morbid responses in the internal organs in all those we operated on, excluding the few cases which were considered to have come to death from infection due to the operative procedure.

Our anatomicopathological picture, however, corresponds in most respects with that found by Matsuyama, while the school of Sauerbruch (Schmidt) and Mayeda do not agree with Matsuyama and therefore not with our findings. All these experimenters have made use of celostomy. The difference in effect may be attributable either to the age at which the rats came to operation, or to incomplete humoral fusion as a result of the operation.

At any rate, the fact is significant that Matsuyama and ourselves obtained histopathological findings in the internal organs which so closely correspond—the alterations described in the male and female sex glands (denied by Mayeda) and modifications in the anterior pituitary lobe. Still, we differ from Matsuyama in certain findings regarding the adrenal gland, whose cortex we found poor in phosphatid and cholesterin lipoids, while he found it abundant in these just as in states of pregnancy and castration. And furthermore, we are increasing our observations of primary histological results in the thymus, which Matsuyama says are generically atrophic when he is discussing (in the first part of his work) the outcome of parabiosis in general on the liver, on the spleen, on the pancreas, on which organs no one had previously concentrated attention by a special study of parabiosis between individuals of different sex.

Matsuyama, as we saw at the outset, considers all his findings to be related to the changes in the sex glands, which are the first to be established in pairs of male and female through a humoral antagonism exercised over one another by the two partners of opposite sex. Effecting thus a reciprocal autocastration, he is led to find a correspondence between alterations in the other endocrine glands of rats in parabiosis and those encountered in castrated rats or in females in a pregnant state. The increase of large basophiles in the pituitary gland and of lipoids in the adrenal cortex are definitely phenomena common to these latter conditions and to parabiosis, and result from the modifications which take place in these conditions in the sex glands.

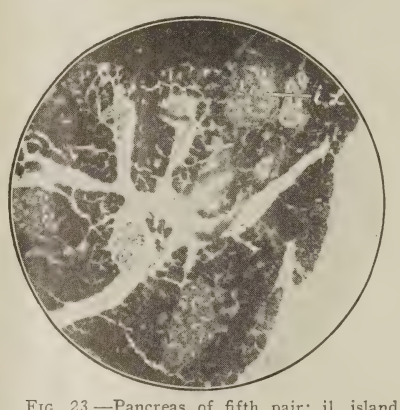

Fig. 23.—Pancreas of fifth pair; il, island of Langerhans.

Such a comparison of the three conditions, of which one, pregnancy, is purely physiological, appears a little too artificial and conventional. Even recognizing that there are many points of affinity, these cannot be grasped in a single clinical and anatomicopathological picture. It is quite true that in pregnancy there is an arrest of follicular evolution and production of a hypertrophic corpus luteum, as Matsuyama found in the first stage of parabiosis, but from this condition to complete castration is a long leap; for this latter removes from the organism the highly important internal secretion of the thecalutein cells of the corpus luteum and interstitial gland, and the effects of castration in all the other glands are exceedingly variable. Enough to mention the thymic hypertrophy which is one of the most characteristic effects of castration, while in pregnancy and in parabiosis we have proved that just the opposite takes place. There is a correspondence only in the anterior pituitary lobe, but it happens that the appearance of large basophile cells in this gland is met with in a great variety of altered conditions of hormonic correlation in the organism (for instance, in goitre), a fact which robs these particular conditions of the attribute of specificity. And the correspondence between the lipoid hypertrophy of the adrenal cortex in pregnancy and castration and that in parabiosis does not exist for us, our adrenals always proving hypotrophic, on the contrary, in regard to these elements of their composition.

Avoiding any preconceived finality in the interpretation of our results, we are inclined to this pro-

visional explanation: The pathological reactions in the glands of internal secretion and other internal organs in parabiosis between male and female are not due to a primary antagonistic toxic action on the part of the testicular and ovarian hormones, as Matsuyama maintains. If they were, it would be difficult to explain, for example, how testicular grafts in hens incompletely ovariectomized can produce individuals with intersexual characteristics developing in complete wellbeing (Pézard, Sand, and Caridroit). The entire organism of male and female, tuned to a response which is specific for each sex respectively, joins in rendering the humoral fusion of a male with a female more toxic and less well supported by the two participants than that between members of the same sex. Between these latter, in fact, there are established from the very beginning toxic relations which cause the excessively sensitive thymus gland to exhibit promptly a morbid reaction. It is logical to assume that two organisms of the same sex, being alike in their internal metabolism, would bear their humoral combination with better success than those of different sex.

But in parabiosis of male with male we found a beginning of alterations in the testicles, and Nissen, who has fully confirmed Matsuyama's experiments, has recently affirmed that the alterations in the sex glands are the same in advanced phases in pairs of male and female as in those of male and male or female and female. This agrees with our point of view, that the primary cause of the reciprocal change is connected with the dysharmony occasioned in internal metabolism by the fusion of the two organisms independently of sex.

Regarding the reactions of the internal tissues in such dysharmonic parabioses we report as follows: Experiments conducted by other methods have already demonstrated the intimate functional relations between the sex glands, the adrenal cortex, and the thymus, and one of us (Pighini) has also evoked them in his different studies of vagotonia, of thymectomy, and of adrenalin intoxication in fowls. These are the three glands which together withstand the assaults of various kinds made on the internal chemism of the organism; and thus in protracted fasting, in avitaminosis (from lack of vitamine B), under x ray treatment, as well as in the vagal alterations referred to and in adrenalin intoxication, we have found more or less pronounced degeneration of the testicles and ovaries, scarcity of lipoids in the adrenals, atrophy of the thymic cortex, while thymectomy is followed by very evident lesions in the ovaries and testicles and lipoid rarefaction in the adrenals.

(*To be continued*)

Atypical Angina Pectoris*

JOSEPH BARSKY, M.D.
New York

Of the vast variety of cases that we have followed in our cardiac clinic, I wish to speak of those that presented frank anginal symptoms, and especially of that small number of cases presenting symptoms which deviated from the classical anginal picture.

I would define angina pectoris as a painful sensation of severe and terrifying character starting usually, though not always, at the middle or upper part of the sternum, and radiating to the left chest, back, arm and forearm, mostly on the ulnar aspect. At times the pain may start at distant points, and radiate towards the sternum. The sensation of pain is usually followed by hyperalgesia in the same areas. Most cases end fatally.

Before proceeding with the description of angina pectoris, it would be appropriate to state some of its causes and the pathological findings.

1. *Coronary disease.*—In this country, most clinicians believe that coronary disease is the cause of angina pectoris. It is only necessary to state that many cases of angina pectoris coming to autopsy show none or only slight disease of the coronary vessels. On the other hand, there are many cases dying of myocardial insufficiency due to coronary involvement that never presented any anginal symptoms. If coronary thrombosis or embolism causes any anginal symptoms, it would be reasonable to expect that many cases showing such lesions would be subjects of anginal attacks. Willius, who studied eighty-six cases of coronary disease that came to autopsy, found that only twenty-two per cent. gave a history pointing to anginal paroxysms. In view of this fact, how can we assume that the diseased coronaries were the causative factor of the attack? It is true that the sudden occlusion of a main coronary vessel may be the immediate cause of death, but this is entirely different from the death during an attack of angina pectoris. A patient may have many attacks of angina and live for years.

2. *Vasoconstriction.*—Other clinicians and pathologists maintain that anginal symptoms are due to a vasoconstriction of the coronary vessels. This theory is rather attractive as it explains the absence of the coronary or cardiac lesions in cases at autopsy. The basis of this theory is analogous to other conditions dependent upon vasoconstriction. No one has, however, ever seen the constriction of the coronaries, nor is the existence of vasomotor nerves to the coronaries accepted by all physiologists.

3. *Sudden increase in blood pressure.*—Dr. Reed in an able article advanced the theory that a sudden increase in the blood pressure may bring on an attack of angina pectoris. He bases his theory upon the fact that exercise always increases the blood pressure and that this may bring on a paroxysm. Just as a breath of air may bring on an agonizing pain in cases of trifacial neuralgia. Still, the breath of air is not the cause of the neuralgia. An increase of blood pressure may explain an anginal attack when it occurs in an apparently healthy heart. Hypertension cases

*Abridgement of paper read before the Williamsburg Medical Society, March 9, 1925.

of this nature present themselves with symptoms both of hypertension and angina. A comparative study of hypertension patients with anginal symptoms and those without such symptoms has not been fully made.

4. The most important etiological factor as claimed by Allbutt is an inflammatory condition about the suprasigmoidal portion of the aortic arch. He believed that the suprasigmoidal portion is the most sensitive part to pressure changes, terming it the sensitive tambour, and that in cases of angina, it is the seat of a definite pathological process, especially in its outer coat. This process may be acute, subacute, or chronic, and either bacterial, such as rheumatic, influenzal, pneumococcic, or syphilitic, or metabolic as in diabetes or gout. He contends that there is always some clear cut pathological process about this portion of the aorta. All anginal cases examined very carefully by a competent pathologist revealed at autopsy some such lesion. Allbutt brought a wealth of material to support his view and a careful study of his work cannot but seem convincing.

However, even Allbutt left unsolved the perplexing and important point as to what factor is responsible for the paroxysms. It is indeed strange that in all the discussion upon the subject of angina pectoris, practically nothing is said as to the immediate cause of the paroxysm. What brings on the attack?

It is my opinion that the existing or determining factor may be a protein poison from food which may gain entrance into the circulation whenever there is an increased permeability of some part of the gastro-intestinal tract and act as an irritant to the aortic plexus, or it may happen that a member of the guanidin group may act by unduly raising the blood pressure in the aorta that can ill afford any additional stress.

The same could be induced by bacterial toxins circulating in the blood and in this way act as an irritant upon the nerves and thus bring on an attack. The paroxysm will last long enough until the body cells will fix or neutralize the poison, and then the attack is over. In a heart that is not much diseased, the patient may recover. A heart that is the seat of marked pathology such as coronary disease will succumb.

In the presence of some definite pathological lesion, a physical or emotional factor may be an exciting agent. A strong emotion may produce the same effect by raising the blood pressure. Walking up a hill, or against a moderate wind will bring on an attack. In support of this view, we do not have to go far. Asthmatic paroxysms we know are brought about by the protein products circulating in the blood stream of sensitized individuals and as soon as the body tissues fix the poison the attack subsides.

The symptoms as described by the patient are that upon any exertion such as walking up a flight of stairs, running after a car, or lifting up a heavy weight, he is seized with a sudden pain. The patient may even be awakened from his sleep by the pain. At first the pain may not be so severe, but gradually increases in intensity. It may be of a tearing character situated under the upper part of the sternum and rapidly spreads in the direction of the brachial plexus, producing a numbness, burning and painful sensation in the left chest, shoulder, and extending backward between the scapulæ along the arm, forearm, wrist and medial two fingers. The pain may radiate upward along the cervical plexus and cause a most atrocious pain in the neck, back of the head, chin and lower jaw up to the ears. Sometimes the pain darts across the chest to the right side only. Occasionally the pain and radiation extend to both sides of the chest with equal intensity. At times the pain is situated in the epigastric region and as it often happens following an attack the patient belches up gas or vomits, he attributes his trouble to the stomach and seeks relief for the gastric distress.

In addition to these viscerosensory reflex phenomena some patients also exhibit visceromotor disturbance. There is a sensation as if the breast bone is being crushed, pressed or driven in toward the spine. He remains as if transfixed, daring not to breathe lest he lift up his breast bone and increase the agony. At times a sickening, sinking, drawing feeling in the epigastrium causes the patient to feel that he will faint or even die if the pain continues much longer. During the attack the sufferer becomes pale, covered with a cold perspiration, grows apprehensive and there is an expression of terror in the eyes. Even if the physician arrives after the paroxysm he is made aware of the terrible struggle the patient has gone through not only by the appearance of the patient, but by the frightened looks of the bystanders as well.

Needless to say, not every patient will exhibit all the symptoms described nor is the intensity of the pain the same in all patients. What is most important to remember if we are to recognize an atypical case is the fact that any one symptom instead of starting in the midsternal region radiating upward or downward (as described), the reverse may occur. Instead of having a combination of all the symptoms the patient may have one symptom only, for example, a pain of terrific nature in the wrist only, or in the shoulder, intercostal muscles, a choking constriction in the throat. All these symptoms or even one may be none the less dangerous.

The first attack may kill or the patient may have many attacks, eventually dying of heart failure. To confirm a diagnosis all cases should be examined for hyperalgesia in the distribution of the painful areas.

The physical examination of patients who, if prior to the attack, were free from organic heart lesions, gives us negative results. The pulse rate is not increased and is regular if it has been so before. I have had the opportunity of measuring the blood pressure in several cases during the attack and in one case only was there a rise of blood pressure. It is quite conceivable that the pain itself may increase the blood pressure. Electrocardiographs taken of a great number of cases by Willius and others did show several abnormalities, but not distinctive for this condition. Fluoroscopy may show an enlarged aorta but considering the age of the patient, this is not necessarily abnormal. Instrumental examination will not aid us much. Our clinical sense and a familiarity with this symptom complex is our only guide to the correct diagnosis.

The French maintain a sharp distinction between the angina of effort and the angina of rest. In my opinion, they cannot be sharply differentiated and

separated for they blend into one another. Some anginas start at night only and later attack the sufferer on the slightest effort and vice versa.

It is my experience that these night attacks are as a rule more violent and accompanied by greater mortal fear than those attacks which come on with effort. In attacks brought on by effort, the provocative cause of the immediate attack is purely physical and is under the control of the patient. He can regulate his effort or stop it altogether at will with the relief of his symptoms. Not so with the night attack. Here the sufferer has nothing to do with bringing on the paroxysm but is stricken down in the dark as by an invisible enemy. The patient remains in agony until his body tissues take care of the exciting factor whatever that may be and only then does he get relief. In this case, the excitant may be a protein poison, a bacterial toxin absorbed from the gastro-intestinal tract, or a retention in the blood of some substance that is ordinarily eliminated by the kidneys and this substance acts as an irritant to the aortic plexus.

I will cite the records of a few typical cases which will illustrate the remarks that I have previously made.

Case I.—Patient was sent into the hospital by Dr. H. E. Isaacs for the removal of the prostate. Patient had had urinary disturbances for some time due to prostatic hypertrophy. Dr. Isaacs requested the examination of the patient as to operative risk as he did not consider the patient in the best condition.

The patient was a man fifty-six years old, but looking older. Not of the robust type, but by no means sickly looking. His previous medical history, with the exception of the prostatic enlargement, was of no importance until about ten days prior to his admission to the hospital. The physical examination of the chest gave the usual findings of a man of that age—slight emphysema, cardiac sounds rather weak, partly due to the emphysema and probably myocardial weakness; first and second mitral partook of the same quality, aortic second not accentuated. No enlargement was noted. Pulse was regular and equal, not much evidence of sclerosis in the radials. Blood pressure not raised.

Ten days prior to his admission to the hospital, he was suddenly seized at night with a terrific pain in the left chest. He could not locate the exact starting point but it involved the entire left chest front back and shoulder. Breathing or any movement increased his suffering. He had several physicians during that night and all diagnosed the case as pleurisy, and gave him a hypodermic medication with little relief. In the morning, he had a consultant who confirmed the diagnosis as pleurisy, advised strapping of the chest, but with no relief. He suffered for about thirty-six hours, could not breathe or turn to the other side for the pain was excruciating.

He was relieved of his suffering after thirty-six hours and began to have a slight rise in temperature to 100-100°. At this point, moist râles, diminished breath sounds were found; the case was diagnosed as a probable bronchopneumonia. The elevation in temperature lasted about three days. On the sixth day he was free from all symptoms and out of bed. On the tenth day he came to the hospital.

In analyzing the case, I had no difficulty in recognizing the case as atypical angina pectoris presenting a combination of the viscerosensory and visceromotor types. I advised against operative interference. In this case, the hypertonicity of the intercostal muscles was such that the slightest turn of the body or even a deep inspiration increased the agony and gave symptoms resembling pleurisy. The latter condition, however, has not the dramatic pain and can always be relieved by morphine. Next day the patient was taken to the x ray room. While there he uttered a cry of pain, clutched in the region of his heart, gave one gasp and died.

Case II.—On the 13th of December, I saw a similar case, that of a druggist, thirty-four years of age. He gave a history of having had grippe six weeks previously. He was confined to bed for some time and made a good recovery. Three weeks later he was seized with a terrific pain in the entire left chest. The pain could not be relieved by morphine. Because of a few moist râles and slightly diminished breath sounds at the base of the left lung, the physician diagnosed the case as pleurisy. He was kept in bed for two weeks and one morning when he felt well he went down stairs to go to the store. He was seized with an agonizing pain in the upper sternal region and had to remain on the spot for fifteen minutes until the pain subsided. Now he has paroxysms of pain on the slightest exertion. At present, he suffers from cardiac insufficiency, dilated heart, enlarged liver, congestion of the lower bases of the lungs and is confined to bed. A cardiac infarct has probably developed which, if the patient lives long enough, will result in an aneurysm and rupture.

Urine and blood were negative. Wassermann was negative. Blood pressure was 100-70. This condition started as an atypical case and was diagnosed as pleurisy. These two cases illustrate the viscerosensory and visceromotor types.

Case III.—Male, aged fifty-six years; appeared much older. Keeper of a small grocery store which entailed hard work and long hours. He had both legs amputated for thromboangiitis obliterans several years ago, healing with good result. He had no other diseases before amputation or after. Though not of a very robust type, he enjoyed fair health, attending to the store, until a year and a half ago when he was attacked with a constriction of his throat and a choking sensation. There was no pain, but a feeling of strangulation and a fear that should it continue he would be suffocated. It lasted a few minutes and passed off leaving him covered with profuse perspiration and somewhat weakened. He had several attacks. During the eighteen months he had seen several consultants and the case had been diagnosed as globus hystericus. I was called in one evening to see him. When I arrived the proxysm was over. This time the attack was more severe, lasted longer and the patient felt more exhausted, more frightened than on previous occasions. I took a detailed description of his case and was assured that at no time did he have any pain sensation. The last attack was in no way different from the previous attacks, with the exception of the severity and that this time he felt completely exhausted, for he presented the appearance of shock. His face was waxy, eyes strained, pulse feeble, about 90, blood pressure 90-60.

I diagnosed the condition as angina pectoris, of the visceromotor type. In this case there was not enough reflex sensory phenomena to evoke pain, but heightened tonicity of the muscles of the neck gave the sensation of strangulation. I gave a fatal prognosis. The patient died twelve hours later.

Case IV.—Male, fifty-six years old, tailor, always well, robust physique and unusually well preserved and of a cheerful disposition. Never had occasion to consult a physician or a dentist in his life. Two weeks ago, while walking home from work, he felt a sudden burning in the epigastric region. It was so severe that he could not proceed home but had to stop at the nearest drug store, where he was given something which relieved him of the sensation. The burning lasted for fifteen minutes, during which time he did not attempt to move for he could not. Two weeks later, at about 3 a. m. he awoke from his sleep with a terrific burning in the epigastric region. In addition to which he had a sickening feeling. The burning was so severe that the family had to summon a physician. By the time the doctor arrived, the condition had somewhat improved. The patient was given a hypodermic and was told he had stomach trouble. When he presented himself at my office for examination, his chief complaint was dyspnea on exertion. He had a feeling that he had stomach trouble. The physical examination, including the urine, was negative. No cardiac or aortic enlargement was made out on percussion. Pulse was regular and fair in volume. Blood pressure was not increased. This is a case of purely sensory phenomena. Of course, we may raise the question if this case should be included in angina pectoris. But the rapid onset and the rapid termination and the severe burning, sinking sensation and the fact that after the second attack, he began to show myocardial symptoms, would in my opinion, justify considering the case to be one of angina. There is one other question —whether the patient did not mistake the pain for burning. To my repeated interrogation and explanation of the difference between pain and burning, he was of the opinion that it was burning. He never had any pain in any part of his body. This case is purely of the sensory type.

The following case is of interest on account of the fact that the pain started in the left arm, at times in both arms, radiating backward and forward in the chest.

Case V.—The patient, male, sixty years old, teacher by profession. He felt well until six years ago, when on walking he began to experience a pain in both legs so that he would be forced to stop. After resting, he would be able to proceed. He never took long walks on account of this pain in his legs.

Two years ago, the pain in his legs subsided and on exertion he began to experience a pain starting in the left arm sometimes in both arms, radiating to the back and upper sternum. Lately he gets pain even at night and it is more severe in character, so that it has practically invalided him for the past few weeks. Pain is now present after the slightest exertion. Marked dyspnea is present.

Physical examination is not remarkable. There was emphysema and signs of chronic bronchitis. Cardiac sounds were weak, belllike in quality. No cardiac enlargement to percussion due to emphysema. Pulse 74 and regular. Blood pressure 120-80, blood normal. There were free traces of albumin in the urine. The patient died three months and seventeen days after I saw him.

In later development, the patient showed symptoms of cardiac decompensation, and contrary to the prevailing opinion that when decompensation sets in the attacks cease, the patient died during an attack at night while at complete rest. This case illustrated the unusual starting point.

Case VI.—Male, age forty-four, admitted February 17th, discharged March 14, 1923. Six years ago he began to have pain, supposed to be colicky in the right upper quadrant radiating backward and toward the right scapula. It was necessary to give morphine for the relief of the pain. Between attacks the patient felt well. The case was supposed to be one of cholelithiasis.

Physical examination showed the left heart enlarged, enlargement of the aorta and a systolic blow at the apex. The pulses were equal, the blood pressure 202-100. Wassermann reaction was negative. There was slight rigidity in the upper right quadrant and the liver was slightly enlarged. Laparotomy was done and negative gallbladder findings resulted. The mesenteric arteries were sclerotic. The patient died in an attack shortly after leaving the hospital.

Case VII.—Female, aged seventy-two years, had been sick for about three years with all possible conditions suspected. Her gastrointestinal and skeletal systems had been x rayed with negative results. She had no disease bearing on the present illness. Three years ago, she began to have a pain of gnawing pressing character in the upper left quadrant radiating at times to the right chest and up or down in the abdomen. At first the pain came in paroxysms, but later the pain was almost constant according to the children from whom the history was obtained. The patient herself was not intelligent enough to give a detailed account. From all the conflicting details that were obtained from the family, a few facts definitely pointed to angina.

While the patient was continually complaining, there were times when the family were obliged to call in a physician. She suffered such an attack the night before she was admitted to the hospital. She was seized with a terrific pain in the abdomen which caused her to faint. The attack lasted about an hour. Morphine did not relieve the agony.

The woman had lost forty to fifty pounds in weight within the last three years. During her eleven day stay in the hospital, clinical findings were negative, gastric analyses showed absence of free hydrochloric acid, blood pressure 116-70, Wassermann negative, x ray of the skeletal and gastrointestinal systems negative. A few days after the patient left the hospital she had another attack of abdominal pain and died.

These cases cited were selected from my case records for the purpose of illustrating the points brought up in this paper. Nothing can be gained by citing more cases. I have attempted to throw some light on a subject which is beset with great difficulty. This difficulty I have sought to overcome and I hope my efforts will be of assistance to you.

127 West Eighty-sixth Street.

Practical Therapeutics

The Action of Allergic Components in the Pathogenesis of Arteriosclerosis and Its Treatment Directed to the Cause with Animasa

CARL FUNCK, M.D.
Köln, Germany

Drawing on observations on a large number of patients, in my capacity as chief of section on internal medicine at the local Trinity Hospital, I designated (1) in 1913 and 1914 a group of forms of diabetes and the majority of the arteriosclerotic and hypertonic affections as impairments of adult metabolism caused by the passage of products of portein cleavage, foreign to the blood, through the intestinal mucosa and by the abnormal permeability of the filtering organ, the liver. I proved at that time the presence in the blood of these products of protein cleavage in a series of cases of diabetes, of intestinal autointoxication, cirrhosis of the liver and gastroenteritis. These relations between alimentary intoxication and diabetes have recently been somewhat confirmed by the success achieved in von Pirquet's clinic with insulin (2) in a series of nondiabetic children who were suffering from a severe alimentary toxemia. Correspondingly diabetic coma and the intoxication of children who are suffering from toxic alimentation with products of protein cleavage are essentially related processes and should be treated by the selfsame organic preparation.

These connections as to cause were subsequently confirmed by Widal (3), Spillman (4), Coca (5), Frugoni (6), Kämmerer (7), Laroche (8), Pagniez (9), and Nast, by Storm van Leeuwen (10) for asthma and migraine. Hulse (11), Vollhard (12), Kuczynski (13), Sokoloff and Atschnikoff (14), Heteny (15), Fox (16) and other authors confirmed the importance of products of protein cleavage, foreign to the blood, in the genesis of diseases of hypertonia and arteriosclerosis. It is surprising, however, that the above mentioned authors draw no general conclusions regarding the pathogenesis and therapy of the cases of arteriosclerosis that they observed, in spite of their positive clinical and pathologicoanatomical findings.

The parenteral digestion of the proteins and its relation to the arteriosclerotic diseases as being of causative nature has, true enough, had great attention paid it in the above cited recent literature. On the other hand, the study of its clinical effect was made difficult by the long duration and the torpid form of pathological process of arteriosclerosis and investigators were confining themselves mostly to the investigation of the generally similar forms of allergic affections, like hay fever, bronchial asthma, migraine, which are acute and easily controllable, because presenting acute swiftly passing symptoms. May I mention, among many others, the experiment of Hajos (17) who was able to abort attacks of allergic asthma in a series of asthmatics, by means of certain proteins (pork, eggs) only when the gastrointestinal cause had been previously damaged by the addition of cognac, i. e., been made permeable to portein. Though Storm van Leeuwen does not take the intestinal mucosa as a gate for the passage of protein bodies, foreign to the blood, but tries to prove sensitization by way of the bronchial mucosa, in a large group of allergic asthma and hay fever affections. This geographical shift of the gate of entrance nowise changes, in principle, the conception of the pathogenesis of these groups of affections. Nay, it rather strengthens the force of the proof contained in it, since it generally arrives at the same view of the pathogenesis although starting from divergent observations.

Let us now assume with the authors quoted above that on the majority of the arteriosclerotic affections, except those arising from an intoxication of specific infection, especially lues, there is a pathological permeability of the intestinal mucosa, and of the hepatic filtering mechanism, for products of protein cleavage. If so it appears consistent why Lowenthal (18) established two main factors and conditions for the production of experimental arteriosclerosis in rabbits by way of introduction of cholesterin, namely, first the introduction of large quantities of protein, and second, injury to the liver so that cholesterin cannot be excreted altogether, or completely, but that, on the other hand, products of protein cleavage foreign to the blood, could pass through the filter of the liver. True, we cannot simply draw an analogy as to the pathogenesis of arteriosclerosis in omnivorous man from the herbivorous rabbit, because the multiplicity of the pathogenic factors is infinitely greater in man. But the relations that Lowenthal discovered are so exactly in agreement with the causative factors, so far proved for the pathogenesis of human arteriosclerosis by Kuczynski, Vollhard, and other authors by means of pathologicoanatomical findings, that their agreement is most striking. Again the causes are first, the rise of continuous states of angiospasm (*status angiospasticus*) by the action of products of protein cleavage foreign to the blood; secondly, the surcharging of the blood with cholesterin, and thirdly the degeneration of the endothelium of the angiospastic bloodvessels and the infiltration of these degenerated cell heaps with the cholesterin that copiously circulates in the blood. Similar reactions of the vascular walls are also known to take place in the course of insidious chronic anaphylaxis in other affections, especially in the anaphylactic enteritis of Schittenhelm and Weichard, in cases of mucous colic described by Foges (20) and others. Naturally not all products of protein break down which cause an angiospasm, hail from the gastrointestinal tract, but may, for instance, get into the blood stream through a dysfunction of endocrine glands. This I have proved in individual forms of diabetes for the pancreas. This is likewise well known from the ovarian dysfunction at the climacterium with the vasomotor

disturbances constantly appearing in conjunction with it, and with the hypertonia that often hangs over this period.

The general importance of the products of protein cleavage, foreign to the blood, in the rise of the autochthonous or idiopathic, or cryptogenetic arteriosclerosis, is paramount. The other toxic or infectious causative factors in the pathogenesis of arteriosclerosis, like nicotine, lead poisoning, lues, show far less in frequency of occurrence and are of lesser importance.

At any rate the pathologicophysiological and pathologicoanatomical and clinical investigations by the different schools of thinkers and investigators within the last twelve years who have attacked the question from the most diverging viewpoints, have confirmed my contention expressed in 1914. Then I stated that the greatest number of the arteriosclerotic affections are a nutritional disturbance in adults, and are essentially caused by the passage of products of protein cleavage foreign to the organism by way of the intestinal wall into the blood, and by dysfunction of the filter mechanism of the liver.

Therapy has followed these advances in the knowledge of the pathogenesis of the allergic diseases slowly and step by step. At first, successes were achieved on a purely empiric basis, in asthma, by means of tuberculin injections, later it was found that these tuberculin injections will also lower blood pressure. The parenteral utilization of the most divergent products of protein cleavage, whether due to x ray irradiation or from a tonsillitis or influenza, proved likewise able, in many cases, to improve at times asthma and migraine and to lower blood pressure transiently or permanently and to influence favorably the symptoms of arteriosclerosis, even angina pectoris (Hajos). From the recognition of this fact it was no great step to the attempt at desensitization whether specifically as van Leeuwen demonstrates it in asthma and hay fever, or unspecifically as other authors have employed it successfully in asthma, migraine, hay fever, urticaria, likewise, in cases of arteriosclerosis and hypertonia by means of injections of milk deuteroalbumoses, vaccines and other products of protein cleavage, Kylin (21), Hajos. The successes attained by Heilner, Major and others with injections of organic extracts in arteriosclerosis and hypertonia should certainly be ascribed to the same essential curative factor, namely, the nonspecific antiallergic treatment.

Yet, in the arteriosclerotic affections, the injections of products of protein cleavage and organic extracts, if injected intravenously in accordance with the demands of their authors, produce dangerous reactions and at least discomfort to the patients. This fact limits their employment to a small group of cases only. Now, since the passage of foreign products of protein cleavage through the intestinal wall has been proved to be the cause of the majority of the allergic diseases, *desensitization by the same route must also be possible.* For the other allergic diseases authors like Widal, Pagniez and Nast, van Leeuwen and others, have often proved the possibility of a desensitization by the oral route, only a few special products of protein cleavage seemed to have been fit for oral treatment in the arteriosclerotic disease, although Professor Lichtwitz (22) has even aborted angina pectoris by the simple oral administration of peptone, and the authors of Gilbert's school (France) Parturier and others administer successfully, for desensitization, before meals, a small dose of reduced protein (albumin) in spasms of the cholic passages (Gallenwege).

With the organic preparation animasa a truly specific, orally active product of protein cleavage in arteriosclerosis was produced, which passes safely through the intestinal mucosa into the circulation and acts by desensitizing, by reducing blood pressure and relieving the continual angiospasma. The reports of Professor Griesbach (23) (University of Giessen), Professor Carl Lewin (24) (Berlin), Privatdozent Blumenfeldt (25) and Cohn (Berlin Charite), Funck (26) and many others prove the very eminent specific therapeutic action of the organic preparation animasa in the arteriosclerotic diseases and hypertonia. Without doubt this special activity of the organic preparation is conditioned upon the combination of the specific active products or protein reduction with an extract obtained from the intima and media, the potency of which Professor Heilner has proved by means of injections. This organotherapeutic curative factor, animasa, is so well combined with the product of protein cleavage, that it, or its active factors, pass through the intestinal wall unchanged. This therapeutic action of orally administered specific products of cleavage of the protein of organs has been observed and confirmed in other affections of organs, as for instance Brack recently, by using reduced liver substance in liver diseases, or Brugelman, by using ovarian substance that has been built up instead of reduced.

Authors like Griesbach, Migeod and others emphasize in their appraisal of the curative action of the organic preparation animasa, above others, its pressure lowering action and have proved it both by way of experiment and in the clinic, and have especially recommended animasa for arteriosclerosis just because of this pressure reducing action. I personally am reaching the conclusion, on the basis of clinical examinations for six years, and judging from results, that animasa surpasses by far for its curative action directed at the cause, all so far available means, but I am reaching this conclusion on the basis of other considerations and observations, to wit, that hypertonia is only one symptom of the disease called arteriosclerosis and the amelioration of this one symptom cannot be the only criterion for evaluating a cure for arteriosclerosis. We must rather conceive the disease in all its extent in evaluating this curative action. I have become convinced far more than by the mere simultaneous lowering of blood pressure of its far reaching effect that aims at the cause by the improvement which it causes in the general well being, by the restoration of the efficiency for work, even for difficult mental work, of alertness, in short of mental health, by the abolition of premature fatigability and sleeplessness, all of which I repeatedly found in the use of animasa. This general action of animasa was established also in grave cases of arteriosclerosis even when the lowering of blood pressure was not considerable, due to advanced contracted kidney or toxic factors.

It must be apparent to the physician who thinks in terms of biology, that the pathogenesis of arterio-

sclerosis cannot be explained in accordance with one scheme. The multiplicity of the special causative factors of the disease, the interfering actions as those of poisons, infections and other factors are obscured and fundamentally influenced by one big general causative factor. This factor is the predisposition which again depends upon the peculiarities of metabolism, especially the protein reduction upon those of the intestinal wall, the liver and the intermediate metabolism. Recently Weichardt (28) thought the rise of tuberculosis to be conditioned also upon the present of toxically active products of protein cleavage and to be curable by desensitization against these substances. Hans Much (29) likewise considers a constitutional "dysiminunity" (anaphylaxis) towards metabolic products of protein cleavage as primary cause of many systemic affections.

The organic preparation animasa answers most comprehensively the demands made upon it by the biological, physiological and pathological findings, and can therefore be designated as the first causally (that is, directed at the cause) and prophylactically active remedy for such cases in which heredity or conditions of living make probable the development of a premature arteriosclerosis. I prescribe this remedy in accordance with my experience, and still more extensively in the prophylaxis of arteriosclerosis, without, of course, omitting both in therapeutis, and prophylaxis, the indicated physical and dietetic methods of treatment or a specific therapy in case of special indications (syphilis). The special curative action of this organic preparation is most clearly evident in such cases in which arteriosclerosis has been subjected to a protracted medicating and physical treatment and then the treatments were replaced by animasa or when in beginning arteriosclerosis of middle age (a blood pressure of 150 mm., shortness of breath, mild vertigo, congestions of the head, irritability, etc.) all the injurious living conditions were retained as heretofore injurious for the sake of clinical experiments and yet after using animasa for two or three months objective and subjective cure ensued.

It may happen that with the progress of the biological and biochemical technic a still more powerful concentration of the specific curative elements will be obtained which are found in the organic preparation animasa just as the production of the organic preparation insulin was perfected in the last few years. But in the diseases of arteriosclerosis a therapy directed at the cause and prophylaxis will make use of the principle which underlies the organic preparation animasa.

The Kastle-Meyer Test for the Detection of Blood from the Medicolegal Aspect.—John Glaister (*British Medical Journal,* April 10, 1926) states that from the medicolegal aspect, the Kastle-Meyer test is very delicate and reliable in the detection of hemoglobin. It is apparently a worthy substitute for Day's test, which possesses many fallacies, requires fresh reagents, frequently fails to act when only small quantities of blood are present, and in certain cases gives only a faintly positive reaction, creating doubt in the mind of the examiner whether such should be regarded as positive or negative. There are no "borderline" results. The reaction is well marked, is practically immediate, and time is economized in not having to await soakage of the stains before applying the test, if the watch glass method is utilized. This becomes an important consideration when there are many productions to be examined. The age of the stain does not apparently affect the delicacy of the test. Owing to the extreme delicacy of the test, however, it should be remembered that the greatest care must be taken to ensure absolute cleanliness of all vessels in order to exclude rigidly extraneous contaminations of the vessels as the result of a previous examination.

The technic is as follows: Two chemical solutions are required for the test, one being hydrogen peroxide of strength twenty volumes; the other is composed of a mixture of two grams of phenolphthalein, twenty grams of potassium hydrate, and distilled water to produce one hundred c.c. of the reagent. These three ingredients are boiled, and during the process ten to thirty grams of powdered zinc are added. Boiling is continued until the solution becomes colorless, usually after about ten minutes. About ten to twenty drops of the reagent are added to the suspected bloodstained surface, thereafter adding a few drops of fresh hydrogen peroxide. If blood be present a deep permanganate color develops.

Placenta Previa*

A. LOUISE McILROY, M.D., D.Sc.

London

PART I: GENERAL CONSIDERATIONS AND DIAGNOSIS

Hemorrhage occurring during pregnancy may be divided into two main groups: 1, hemorrhage before the twenty-eighth week, and 2, hemorrhage after the twenty-eighth week when the child is viable. Although the causes of hemorrhage in these two divisions may be identical, it is more convenient for clinical purposes thus to divide them. In the first group, although hemorrhage may be caused by new growths and other pathological conditions of the uterus, these are comparatively rare. For practical purposes it may be taken that in the majority of cases the hemorrhage is due to partial or complete separation of the ovum from the uterine wall, and that the cause is usually accidental or toxic.

Probably a number of cases of hemorrhage and abortion are due to a low insertion of the placenta, but it is seldom that this can be definitely diagnosed. Hemorrhage before the twenty-eighth week is therefore most frequently due to abortion—threatened, complete, or incomplete—or to the retention of a diseased ovum or mole.

Hemorrhage occurring when the child is viable, i. e., antepartum hemorrhage, may be divided into two main groups: 1. Hemorrhage due to the separation of a normally situated placenta—accidental or toxic hemorrhage. 2. Hemorrhage due to the separation of an abnormally situated placenta—placenta previa.

Normally the placenta is situated in the upper zone or contractile portion of the uterus, and protected by the muscular wall of that organ.

A placenta previa is attached wholly or in part to the lower uterine segment, which extends about three inches above the internal os, and is specially constructed to allow of distention. It is scantily supplied with muscle fibres which are longitudinal in direction. The segment becomes thinned out by the presenting part during the process of labor. It also stretches during the later weeks of pregnancy, and during this period the placenta increases in size, when its position becomes more precarious.

When the segment stretches it detaches itself from the placenta. This occurs during the last few weeks of pregnancy but is especially marked during labor. Hemorrhage is therefore an inevitable result. For this reason such hemorrhages are known as unavoidable.

The placenta may be perfectly healthy, but its separation is due to its abnormal situation. A placenta previa may, however, become detached by accident as the result of jolts or jars against the bony pelvis. It is also liable to degenerate toxic changes similar to those which take place in normally situated placentæ. When the placenta is situated normally, separation is due to some toxic degeneration of the decidua, and the condition is associated with toxemia in other directions.

In every case of antepartum hemorrhage, attention must first be directed to possible low attachment of the placenta, as placenta previa is the most frequent source of severe forms of hemorrhage in the later weeks of pregnancy.

It is a matter of controversy whether the segment stretches before labor, but as the presenting part descends and engages in the pelvis during the last few weeks, there must be a corresponding stretching of the uterus to form the lower segment. The frequent occurrence of placental separation before the onset of labor also points to distention of the lower uterine zone. The placenta does not easily accommodate itself to the stretched uterine wall, consequently laceration of the vessels of the decidua takes place and bleeding from the uterine vessels results.

If there is a tendency toward separation of the placenta owing to toxemia, hemorrhage is all the more likely to occur.

At the onset of labor, the membranes become stripped off at the lower pole of the uterus to form the dilating bag. If the whole or a portion of the placenta is situated in this area it must become detached.

From a clinical point of view placenta previa is that condition in which hemorrhage occurs prior to delivery, and it is in most cases only by the presence of hemorrhage that the diagnosis can be made with any degree of certainty.

*From The Obstetrical and Gynecological Unit of the London (Royal Free Hospital) School of Medicine for Women, University of London.

The cause of placenta previa is unknown. Various theories are given to explain why the ovum should become implanted in the lower uterine zone. Among these are the following:

1. That the fertilized ovum, while in process of escaping from the uterus, is caught at the internal os and becomes implanted in its vicinity. Previous uterine disease which cause distention of the uterine cavity is said to be a predisposing influence. There is very slender proof in support of this theory.
2. That an ovum in the upper zone may have its placenta formed from the capsular decidua as well as from the basal portion. Instead of becoming atrophied, the capsular may proliferate and invade the true decidua of the lower uterine segment. The placenta has a capsular instead of a basal origin. This is the most likely cause of the condition.
3. That owing to defective vascularization of the decidua the placenta may be limited in its blood supply, and for this reason a greater area of attachment is necessary for nutriment. This might explain the theory that placenta previa is due to frequently repeated pregnancies, which cause atrophic changes in the uterus.

When the attachment between uterus and placenta is firm, hemorrhage rarely takes place until the onset of labor.

Placenta previa sometimes shows areas of degeneration from defective blood supply, and in some specimens a placenta succenturiata is observed, and also a membranous form.

The cord is frequently inserted at the edge of the placenta—the battledore type.

Placenta previa has been known to recur at subsequent pregnancies.

CAUSES OF THE HEMORRHAGE

Hemorrhage is due to laceration of the vessels in the decidual layer on the uterine wall. The vessels become thrombosed on separation, and in some cases the hemorrhage is automatically controlled. The hemorrhage occurs during uterine contractions, when the separation causes laceration of the maternal, venous, and arterial capillaries. The lower uterine segment is stretched by the longitudinal muscle fibres, by the pressure of the bag of membranes, and also by the presenting part, since the latter tends to descend in the direction of the pelvis and take up its position in the cervical portion of the uterus.

If hemorrhage occurs during pregnancy and before the onset of labor, it may be accidental, from the separation of a defectively protected placenta, or it may be due to painless uterine contractions which occur throughout pregnancy, but are more marked towards the end. These contractions stretch the lower uterine segment, and cause separation of the unstable capsular decidual attachment.

There is no doubt that the cyclic or exaggerated rhythmical action of the uterus which occurs every menstrual period is continued to some extent during pregnancy, and this may explain why the bleeding in some cases is recurrent with several weeks interval. The uterus is more easily sensitized at the time a menstrual period is due. Rupture of a semicircular sinus in the placenta is suggested as a cause of the hemorrhage.

FREQUENCY OF PLACENTA PREVIA

The average occurrence is one in five hundred cases. Most of the statistical information comes from obstetrical hospitals where emergency cases are dealt with, and it is difficult, therefore, to gauge the true rate of occurrence of the condition. Many cases of placenta previa must abort in the earlier months of pregnancy and are therefore not recognized.

PARITY

Placenta previa is said to be more frequent among multiparæ, especially where pregnancies have followed in rapid succession.

TYPES OF PLACENTA PREVIA

For clinical purposes placenta previa may be classified in two main groups:

1. *Complete,* where the placenta completely covers the internal os. As a rule a complete or central placenta is developed more in one side of the uterine segment than on the other, so that a complete centrally situated placenta is rare.
2. *Incomplete,* which has two subdivisions: a, marginal, where a portion of the placenta overlaps the internal os or is implanted at its side, and b, lateral, where the placenta extends to the lower uterine segment but does not reach the internal os. The marginal type is more common than the complete.

No hard and fast classification can be made, as the position of the placenta varies with the degree of dilatation of the internal os. A placenta may be complete at the beginning of labor, and become marginal as dilatation progresses. The degree of overlapping must be carefully considered when deciding upon methods of treatment.

SYMPTOMS OF PLACENTA PREVIA

Hemorrhage is the chief symptom if not the only one in most cases. It occurs without any warning. It is seldom the result of undue exertion. It may commence as a sudden gush of blood when the patient is at rest or even asleep. There may be a continuous or intermittent trickle of blood, or brownish discharge, for days or even weeks. This may be followed by severe and sudden hemorrhage. Hemorrhage may begin at the twenty-eighth week but is more liable to occur nearer term and when labor begins. It may occur, cease, and recur at intervals of four or five weeks as if influenced by the recurrent activity of the ovary. In some cases the patient is collapsed and suffers from shock within a few minutes of the onset of the hemorrhage. Death may occur before medical assistance can be obtained. Apart from labor, pain is not a symptom.

EXAMINATION AND DIAGNOSIS

In the majority of cases the patient appears perfectly healthy if examined before any undue loss of hemorrhage has taken place. There is an absence of symptoms or signs of toxemia, such as headache, nausea, dimness of vision, edema and albumin in the urine. It must be remembered, however, that

these may be present in some cases where placenta previa is a complication of toxemia.

PLACENTA PREVIA SUSPECTED DURING PREGNANCY

In cases where placenta previa is suspected from the symptom of slight hemorrhage, the abdominal examination may be perfectly normal. In some cases it is possible to auscultate the placental *souffle* in the lower uterine area. This sign can be confirmed on vaginal examination and subsequently at labor. It is not always to be found, as the placenta may lie behind the fetus, but when present it is of use as a method of diagnosis.

The fetal parts are felt without any difficulty unless the uterus is contracted. The fetus may be in its normal situation with the head engaging in the pelvis. Sometimes it is in a breech or transverse position and it is said to be due to obstruction of the placenta in the pelvis. It is impossible to be certain of the cause of the malpresentation, as so many cases of hemorrhage occur when the fetus is immature and in process of turning. If allowed to go on nearer to term it would probably turn into its normal head position. The fetal heart sounds are present unless the hemorrhage has been severe. There is seldom any intrauterine hemorrhage.

On vaginal examination an undue softening of the cervix and a pulsating boggy swelling may be felt in the vault of the vagina or in the fornices if the cervix is closed. It may be impossible to feel the presenting part of the fetus and clots may be found in the vagina. If labor has commenced there will be an increase in the hemorrhage during the expulsive uterine contractions. If one or two fingers can be introduced into the cervix, the placenta can be felt and distinguished from blood clot by its firm resistent consistence. Direct palpation of the placenta through the internal os is the most accurate method of making a diagnosis of placenta previa.

Blood pressure may be lowered if hemorrhage has been severe. A high blood pressure would indicate the presence of toxemia. Other evidence of toxemia should be looked for, and a careful analysis of the blood and urine made if time allows.

If the hemorrhage is from a normally situated placenta it may be internal, and in such cases the uterus is very tender, distended and has a characteristic wooden feeling on palpation. The fetal parts are not felt and the fetal heart sounds are absent. On vaginal examination the placenta cannot be felt, although in some cases it is difficult to distinguish blood clot from placenta unless it can be easily broken up and removed by the examining finger.

If there is any difficulty in making a diagnosis it is better to treat the condition as one of placenta previa, as it is of more frequent occurrence. With prompt treatment a fatal ending may be avoided.

It is seldom that placenta previa can be mistaken for rupture of the uterus, which rarely occurs unless from direct violence until labor has been in progress for some time. Rupture occurs when there is some diseased condition of the uterus or definite obstruction to the progress of labor. Previous hemorrhage is rare and the placenta cannot be felt in the lower zone of the uterus. Hydatidiform mole occurs earlier in pregnancy, and the hemorrhage is watery and blood stained with possibly detached portions of the chorionic cysts.

PROGNOSIS

The outlook in the majority of cases of placenta previa is serious. The future welfare of the patient depends upon the position of the placenta and the amount of hemorrhage that has taken place. It is obvious that a patient with a complete placenta previa will run much greater risks than one with a lateral insertion. Hemorrhage is rarely fatal at the first attack, but the earlier the hemorrhage occurs in pregnancy the greater risk of its recurrence. The patient may become extremely debilitated before labor occurs. Much depends upon the amount of hemorrhage and the presence of uterine contractions. The facilities for obtaining skilled aid and prompt treatment are a large factor in the prognosis of the condition.

The maternal mortality averages from eight to ten per cent., although the Rotunda Hospital publishes a mortality rate as low as three and six tenths per cent. The mortality in the Rotunda Field Hospital unit is about six per cent. The majority of deaths are due to hemorrhage or sepsis. In the unit one death was due to hemorrhage and collapse four hours after Cæsarean section, and one to coliform infection, with pneumonia on fifteenth day. A low insertion of the placenta predisposes to a septic condition and manipulative treatment also raises the risk.

The resistance of the patient is lowered by the antepartum hemorrhage. Lacerations of the cervix and vagina are frequent. The uterus may be inert from collapse and blood clot may be retained and become a source of infection.

Primigravidæ with a rigid cervix are more difficult to treat than multiparæ with an easily dilatable os.

Larcerations of the cervix and vagina are not infrequent. Although postpartum hemorrhage is a possible complication, it seldom occurs, but a small loss may easily prove fatal. The placental stage as a rule is rapid. Sometimes the placenta is delivered immediately after the extraction of the child. The placenta is of average size and weight.

FETAL WELFARE

If placenta previa is serious for the mother it is in most cases ultimately fatal to the child. Over two thirds of the deliveries are stillbirths, and many only survive a few hours or days. In the unit out of forty-three deliveries there were twenty-five stillbirths; twelve were due to prematurity, hemorrhage and version; two to hemorrhage and shock; two to prolapsed cord after version. In the nine remaining cases the fetus was dead before admission of patient.

The chief causes of death are prematurity and antenatal asphyxia from separation of the placenta or undue pressure upon its circulation. About seventy per cent. of the infants are born prematurely, either due to the spontaneous onset of labor or to the induction of labor as a means of treatment for hemorrhage. Seven survived birth but died within forty-eight hours. Twelve went out of the hospital alive.

FETAL PROGNOSIS

Podalic version, although the best method of controlling the placental hemorrhage is often followed by death of the fetus. During the operation the dilatation of the cervix detaches part of the placenta and

causes more hemorrhage to take place with asphyxia of the fetus. The manipulations may cause strangulation of the cord or prolapse may occur, owing to the low insertion of the placenta. The breech may control the hemorrhage but its pressure may obstruct the fetal circulation in the placenta and cord.

Malpresentations may also endanger the prospects of the child. The prognosis of the child's life depends upon the amount of hemorrhage, method of treatment chosen and its prompt application.

PART II: TREATMENT

In the present state of our knowledge the prevention of placenta previa is impossible. The utmost that can be done is to diagnose the condition early and prevent its consequences. The interests of the mother should be regarded as paramount. The life of the fetus is at best precarious. Each case must be considered on its merits. No hard and fast rule can be laid down. The simplest treatment is the best as it gives the most successful results in the hands of the majority of practitioners.

It must be remembered that placenta previa is like a pent up dam which may burst at any time, causing death and destruction. When hemorrhage occurs the practitioner must decide the course to adopt—whether to apply active treatment or to leave matters to take their course, keeping the patient under careful observation.

In noninstitutional practice it is a safe policy to deal with the condition promptly when the first hemorrhage occurs. If, however, the hemorrhage is slight and diagnosis doubtful, the other alternative may be adopted. The patient should be warned, however, of the danger and arrangements made whereby prompt and skilled assistance may be obtained should hemorrhage occur. This may happen suddenly, accompanied by the death of the fetus and possibly the mother. Even a patient undergoing observation in hospital may lose her life within a few moments of the onset of severe hemorrhage.

In treating placenta previa much depends on the type to be dealt with. There is a vast difference between the complete or central variety, on the one hand, and the marginal or lateral, on the other. A practitioner who is called upon to deal with a complete condition is faced with a most serious problem. I now propose to describe the different forms of treatment and the best method for each period.

If the hemorrhage is slight and recurring at intervals of several days, and the pregnancy is not advanced as far as the thirty-sixth week, the patient may be kept in bed with precautionary arrangements at hand for immediately dealing with any serious hemorrhage. By this means it may be possible to allow the pregnancy to continue until the thirty-sixth week or after, or, in other words, until the child is given a chance of survival. A child born before the thirty-sixth week may be alive, but when birth is complicated with placental hemorrhage its chances of surviving for more than a few days are small. This line of procedure is only to be adopted in cases of incomplete placenta previa, or where this complication is suspected but not diagnosed with any degree of accuracy.

In cases of complete placenta previa, where the diagnosis is sure, no time should be wasted in carrying out expectant treatment. The condition is one of extreme urgency requiring immediate interference. As the placenta entirely blocks the outlet of the uterus, it is obvious that birth of the child cannot take place unless perforation of the placenta is performed, or separation from the wall of the uterus is brought about. Such treatment will almost inevitably lead to the death of the infant before delivery is completed. In order, therefore, to obtain a living child Cæsarean section is the only operation which gives successful results. Delivery by the vaginal route has a fetal mortality of almost one hundred per cent. But as the interests of the mother must be considered before those of the child, the practitioner must decide upon the advisability of performing the operation and the risks involved.

Cæsarean section is usually advisable if the case is one of complete placenta previa, the pregnancy is at term or after the thirty-sixth week, no previous vaginal manipulation having been made, and the fetus is alive. Also in cases where hemorrhage has not been so severe as to cause collapse and the major operation might inevitably increase the degree of shock. The operation is indicated more frequently in an elderly primigravida than in a multigravida, owing to the greater rigidity of the cervix in the former case, and to the less likelihood of subsequent pregnancies.

The operation is therefore contraindicated when the child is dead or so premature as to give little hope of survival for more than a few hours or days; when the mother is suffering from severe collapse and shock. In the latter condition the fetus is rarely alive so that its interests may usually be disregarded, and in cases where packing of the vagina has been performed, forceps applied or version attempted by the vaginal route. In cases of infective conditions of the vagina or cervix Cæsarean section is usually contraindicated, but when the fetus is alive and near term the risks involved may be compared with those which might follow manipulations of the undilated cervix with inevitable loss of the infant's life.

No hard and fast rules can be laid down with regard to the dangers of sepsis in Cæsarean section. The operation has occasionally justified itself by the production of a living child and complete recovery of the mother, even in the case of patients with lowered resistance. The dangers consequent upon delivery by the vaginal route may be greater than those which may follow operative interference in potentially septic cases.

The necessity for hysterectomy with the object of preventing postpartum hemorrhage or sepsis must be decided when considering the desirability of Cæsarean section; it is very rarely required.

The drawbacks of a prolonged operation, as well as the consequent sterilization of a young patient, all must be taken into consideration. The latter result requires serious thought as the infant does not always survive the operation, and placenta previa is rarely recurrent in the same patient. Besides, apart from the abnormal situation of the placenta, the uterus is usually healthy unless weakened by prolonged or severe hemorrhage. Hysterectomy, therefore, is rarely necessary in these cases. If required, then Cæsarean section has been an unjustifiable operation in itself, and better results for the mother would

have been obtained by the less radical method of version even if the infant had not survived.

If the child is dead or Cæsarean section otherwise contraindicated, treatment should be carried out according to the method to be described under those of incomplete placenta previa. The same applies if the pregnancy is before the thirty-sixth week or near or at term. On examination of the patient we must ascertain if the patient is in labor.

BEFORE LABOR WITH AN UNDILATED CERVIX

If severe hemorrhage has occurred before term and labor has not begun, our first endeavor should be to induce dilatation of the cervix as soon as we have decided upon active interference. In a primigravida the cervix is usually somewhat firm in consistence and the os completely closed. In a multigravida, on the other hand, it is often open and admits a finger without difficulty.

After examination it must be decided whether the cervix should be dilated by slow or rapid methods. As the chief danger in these cases is hemorrhage, two points must be remembered: first, that whatever treatment is decided upon it must not involve laceration of the cervix or further separation of the placenta. Therefore, rapid dilatation of the cervix by forcible means is not generally employed. A patient weakened by severe antepartum hemorrhage is liable to collapse if postpartum hemorrhage occurs, no matter how slight.

The aim of the medical attendant should be the immediate control of the hemorrhage and the postponement of delivery if possible until the mother has recovered from collapse. In this way satisfactory results will be obtained as the uterus will contract when labor occurs and there will be less risk of postpartum hemorrhage.

The hemorrhage may be controlled by what may be described as first aid means, that is, by the application of direct pressure, by packing the vaginal fornices with wool or gauze, or by the bringing down a leg of the fetus and using the buttock as a compressor for the placenta, as hereafter described in more detail. The introduction of dilating bags may also be employed for the same purpose.

It may be possible in some cases to rupture the membranes and then induce the head to fix in the pelvis and so control the placental separation, but this is rarely of much use where the cervix is not dilated and the patient not in labor. Also the head of a premature fetus is not a satisfactory compressor owing to the difficulty of fixing it, and its extreme compressibility. Cases have been described by Willett in which the use of a clamp to the scalp of the fetus and the attachment of a weight, has brought about satisfactory results by fixing the head in the pelvic cavity.

If the os is open and the cervix unduly softened as is probable, the patient may be anesthetized and two fingers gently introduced into the cervix and a leg brought down. This, however, is not always possible and more especially in primigravidæ is it difficult without incurring the risk of laceration.

Packing the vagina is a useful method. It has several advantages, the chief being that with counter pressure of a pad and binder on the abdomen it controls the hemorrhage and at the same time by its reflex action may induce contractions of the uterus.

That stimulation of the cervix and vagina by digital examination causes uterine contractions is frequently proved in the antenatal clinic in ordinary cases of early pregnancy. The uterus may feel soft and flabby on abdominal examination, but when a vaginal examination is carried out the body of the uterus becomes harder and is felt to be in a state of contraction.

Packing the vagina is also of service as a temporary method of treatment when the patient has to be conveyed by ambulance to a hospital or nursing home for further treatment. That there are risks of sepsis after packing no one will deny, but they are not so formidable as the immediate danger from hemorrhage. Although it has been stated that packing is useless unless very tightly performed, there is a risk of lacerating the vaginal mucous membrane by undue pressure and distention. This has to be considered and the packing material should not be introduced in too large a quantity.

The patient is anesthetized and the vulva and vagina disinfected, a posterior and anterior speculum is introduced, the patient being in the lithotomy position. Tampons of sterilized wool wrung out of an antiseptic solution are taken one by one in a pair of pressure forceps and gently packed into the fornices until the cervix is completely surrounded and this is continued until the capacity of the vagina is reached. Sometimes it is possible to introduce a tampon into the cervix and so assist further dilatation, but care must be taken not to cause further separation of the placenta. A pad of wool and a T bandage are applied to the vulva and a counter pressure pad and binder on the abdomen. Gauze can be used instead of wool but it is more expensive. Bismuth gauze is the best as it does not easily decompose when left in the vagina for some time. It is also more easily introduced and removed than the wool tampons. Tampons may be tied on a string kitetail fashion, thus being more quickly removed.

The patient is left quietly in bed until uterine contractions occur when the tampons may be expelled spontaneously. If labor does not take place the tampons can be removed in six to eight hours and a fresh supply introduced if the cervix is still undilated, but this may mean a second administration of an anesthetic, which is undesirable unless version is to be performed. It is advisable to leave the tampons in the vagina for ten to twelve hours as the longer time involves little additional risk. Repeated packing of the vagina seems to increase the risk of sepsis more than a single application. Therefore it is better to leave the packing rather longer than generally advised by most authorities.

If labor takes place or the cervix is found to be dilated or even sufficiently softened to permit of manual dilatation, version is performed.

VERSION

This usually is performed under anesthesia and is a combination of abdominal or external version and the extraction of a leg through the cervix by the vaginal route. For this reason rupture of the membranes is essential before the operation can be completed. External version is performed by an assistant if the head is presenting, the fetal buttocks are made to lie over the brim of the pelvis or if possible

pushed into its cavity. The operator introduces two fingers of the hand (corresponding to the side to which the fetal abdomen is directed) into the cervix, ruptures the membranes with a pair of forceps or stilette, and grasps the anterior foot and pulls it out at the vulva, where it may be fixed by a piece of wool and gauze round the ankle.

It may be necessary in some cases, where the legs are extended along the trunk, or where external version has not been complete, to dilate the cervix further and push the fingers up into the uterus before the foot can be properly reached. In some cases where there is great difficulty in reaching the fetal lower limbs, and where greater dilatation of the cervix has taken place, it may be necessary to introduce the whole hand into the uterus before the foot can be brought down. If it is a case of complete placenta previa, the fingers must perforate the placenta. If incomplete, the fingers are passed up at the side opposite to where the placenta is attached. By traction on the foot the buttock is brought down and effectively compresses the bleeding area. If hemorrhage should continue, traction on the foot will bring about its control. It is not advisable to attach a weight to the foot as the additional force may lacerate the softened cervix or lower segment. The introduction of the fingers may lacerate the cervix or cause further separation of the placenta with a considerable gush of blood, but this will be controlled as soon as the operation is completed. The foot is distinguished from the hand by the heel, the absence of the easily abducted thumb and the ease with which the foot is flexed upon the ankles.

An abdominal binder is applied after version and the patient kept at perfect rest. After the application of vaginal tampons or in cases of version, the usual restoratives for collapse and shock are applied when necessity calls for them.

If the onset of labor is delayed extreme congestion of the fetal leg and buttock may take place from pressure, but if the child remains alive this usually passes off in a few days after birth when treated with warmth and rest. When labor occurs delivery should not be hurried. The usual methods of breech delivery are employed. If the presentation is a breech or a transverse, at the onset of the symptoms the necessity for abdominal version does not arise and the vaginal manipulations are as a rule sufficient.

It is said that placenta previa is a cause of breech and transverse presentations, but this has not been proved. If these presentations are recognized before the thirty-sixth week, it is likely that the fetus is in an unstable condition and would rotate to vertex position if pregnancy were allowed to advance. In normal conditions breech presentations are frequently found up to the thirty-fourth week. Transverse presentations in the majority of cases are those of a breech in the process of turning spontaneously.

The value of version is controversial, but for practical purposes it is the best method of treatment. Version needs no apparatus and the patient does not require the continuous presence of the medical attendant. The risk of postpartum hemorrhage and of sepsis is lessened. Version is a difficult operation where the cervix is rigid, and is unsuitable if the uterus has contracted down over the fetus. For this reason early rupture of the membranes is to be avoided unless it is considered that the child may be born by a vertex presentation.

(*To be continued*)

The Obstetrician

NICHOLAS SCHILLING, M.D.
North Hampton, Iowa

At a time when the champions of mediocrity in the practice of medicine are busy devising ways and means of how not to do it, it may be worth while to dwell for a moment on a few obstetrical aspects of medical education. The mere circumstance that these observations are the reflections of an actual field worker should not invalidate their soundness.

Throughout the history of obstetrics two schools of practice have contended for approval. Representatives of the one have much faith in the healing powers of Nature, while their opponents maintain that the obsession to do nothing for the woman in labor has been the cause of much unnecessary pain and irreparable invalidism. The latter more radical opinion was tremendously advanced by the discovery of general anesthesia and the practical elimination of pathogenic microorganisms from surgical wounds. Moreover, it is no longer an article of faith that the suffering of childbirth is a matter of purification and atonement. Nowadays, a woman who is flickering towards extinction from the effects of futile labor pains will demand relief. That it better be promptly afforded is the insistent and ominous attitude of neighbors, friends and relations. It will get us nowhere to assure them that the patient is engaged in performing a normal biological function and that it is best to "let Nature take its course." To emerge from the ordeal bruised and injured beyond repair, possibly without a baby and barely alive, is no longer considered a satisfactory dénouement in a confinement case. And, only an extreme optimist could contemplate such a result and still continue to "kid himself" into the belief that such a performance constitutes an adequate exhibition of the science and the art of modern obstetrics.

Much systematic missionary work has been done to protect the public against unscrupulous and incompetent general surgeons. The itinerant fee splitting socalled surgical expert has been thoroughly discredited. No such safeguard has been provided for the expectant mother. While our National Government has recognized the need of reform in obstetric practice, a large proportion of the laity and of the medical profession still seems to take it for granted that any old *mænad* of either sex is fully competent to preside at a confinement. Much of the obstetrical

practice done today is about as skillful and scientific as the surgery performed by barber surgeons several centuries ago.

It is true, of course, that nineteen out of every twenty women in this country would deliver themselves without or in spite of any artificial aid. But this very circumstance tends to encourage perfunctory methods of practice. Too much is taken for granted and the element of surprise is introduced. And, to be taken by surprise is to be at a disadvantage. This handicap can be avoided only when it is borne in mind that obstetrical cases are proverbially uncertain in their clinical behavior. In a moment obstetrical shock, an embolus or a bit of retained placenta may convert the most placid puerperal situation into a complicated and dangerous one.

In real dystocia the problems requiring solution are often among the most difficult in all medicine. Borderline cases of pelvic contraction, eclampsia, placenta prævia and tumors of the pregnant uterus are conditions surely calculated to measure exactly the professional stature of the attending physician. Much experience and fine judgment are essential to determine the indications for the administration of pituitrin or for the application of forceps. Whether a version is to be done or whether the interests of both patients are best served by Cæsarean section are, in a given instance, questions that will tax to the utmost the resources of even the master in obstetrics. On the correct solution of the problems enumerated will depend the happiness of a family. The life of a mother and a child are at stake. In other words, to conduct a woman with a minimum of pain and a maximum of safety through a pregnancy and labor is a task momentous and important beyond all economic computation.

It is an old observation that approximately fifty per cent. of all gynecological practice is the direct result of poor and inadequate obstetrics. Government statistics show that twenty thousand women die annually in the United States from complications incident to childbirth. It is very properly contended that these figures are appalling and it is imperatively demanded that they be improved. The presumption is that we shall improve our statistics only by more efficient practice. This will not be accomplished by the monotonous repetition of lugubrious platitudes about the passing of the general practitioner. Nor will it help very much to erect pretentious and stately hospital buildings. In marble corridors and decorated walls there is no conscience, no sympathy, no skill. Physical prowess, hirsute adornment, poise, dignity and an unctious demeanor are all singularly unavailing as a means to improve statistics in childbirth. The one factor which can influence favorably the life expectancy of maternity patients is ministration by the well trained, intelligent, aseptic human hand. That good obstetrics can be done anywhere has been abundantly demonstrated not only by individual physicians in private practice but more spectacularly by the outpatient departments of lyingin hospitals.

The midwife, male and female, blessed with generous physical outlines, fortified with numerous accessory accomplishments and equipped with assurance unlimited is, no doubt, an imposing and awe inspiring institution. But, really, we cannot depend on it to improve results in obstetrical practice. Here, when there has been no improvident delay, the clinical fate of mother and child is determined by the degree of skill exhibited by the doctor in charge of the case. The detection of concealed hemorrhage, the appreciation of the early symptoms of eclampsia or the recognition of a defect in the placenta are not a "job" for even a male midwife. It should be universally admitted that these are problems which require for their solution all the resources of the most observant and skillful obstetrician. In obstetrics, more than in any other human enterprise, a little knowledge is a dangerous thing. Before any man has the moral right to assume independent charge of a confinement case he should have had the advantage of at least three years of special and thorough training in obstetrics. Adequate preparation for his unique and responsible task is the least his ambition and conscience should consider. In that case he will be more concerned about the welfare of his patients than about the fees he may command.

Moreover, it must be emphasized that the most valuable attainments of an expert in the art of obstetrics are not all of an ultraconservative order. There are obstetrical situations when prompt and skillful surgery will alone meet the indications and improve statistics. To postpone Cæsarean section until despair, exhaustion and possible infection have supervened is very poor obstetrics. It is, of course, equally important to realize that a general surgeon without adequate training in the art of obstetrics may become a real menace to a woman in labor. A working knowledge of immunity and infection will enable the accoucheur to speculate with more interest and intelligence on the various phases of preventive vaccination and the vagaries of bacteria as often exhibited in the birth canal during and after childbirth. It will help him to explain why perfunctory and repeated vaginal examinations are likely to be so disastrous in their consequences, especially when they immediately precede Cæsarean section.

Then, too, there is certainly no occasion to deny or to belittle the self evident proposition that the specialist in obstetrics needs to take a sympathetic personal interest in his patients and that clinical intuition and common sense must sometimes modify his more scientific conclusions. Just why it is so generally taken for granted that the man who knows his stuff is necessarily deficient in simple human pity is not quite clear. Possibly it is due to the fact that there is a type of performer whose sole stock in trade consists in backslapping and jollying the relations. To be a clinician at the bedside, a scientist in the laboratory and an artist in the technical execution of his work are the ear marks of a real obstetrician. That no one else shall assume his responsibilities is the divine right of the woman with the badge of maternity upon her.

The qualifications enumerated will not appear unreasonable when we bear in mind the unique circumstance that the clinical fate of obstetric patients is determined not by the learned consultant who may be called in late to view the tragedy, but by the doctor who manages the first stage of labor.

It should be gratifying to all concerned that there can be nothing more characteristic than the determination of the average American husband and father to provide the best available medical attention for his

family. It is true that he is not always able to differentiate the merits of a real doctor from the tortuous designs of a grinning mountebank. But his intentions are the best and the moment he realizes what it is all about mediocrity in the practice of obstetrics, for the want of patronage, will fade out of the landscape. This consummation will not appear so remote when we contemplate in all its manifold activities the achievements of modern public health work. Antenatal clinics will improve statistics by demonstrating to all concerned that it would be about as logical and safe to employ a barber to do an amputation as it would be to have any old *mænad* preside at a confinement.

Pelvic Varicosities

A Discussion of Their Origin, Symptoms and Treatment

HARRY PIKE, M.D.
New York

Notwithstanding the advance of our knowledge of the diseases of the female generative organs, there still remains a group of syndromes offering great difficulty in diagnosis. Many of these symptom complexes undoubtedly have their origin in disturbances of the pelvic circulation. A common lesion of this nature is pelvic varicosity.

Although varicose veins of the pelvic organs are not uncommon in females, this subject has received scant attention in textbooks and the current literature. Nevertheless it is one of considerable importance, especially in view of the fact that the condition can usually be remedied by operative means.

Richet in 1860 described tuboovarian varicocele, or varicosity, as a clinical entity. In America, the initial paper on this subject was by Dudley (1) in 1888. Since that time, there have been few American contributions, the notable exceptions being those by Emge (2, 3), Kelsall (4), and Darnall (5). Reference should also be made to the paper by Fothergill (6) in England.

For a long time, I have been interested in pelvic varicosities as a cause of gynecological disorders. In many cases, clinical observations on the operating table have demonstrated that many of the symptoms experienced with multiparæ with enlarged uteri and displacements of long standing are due not to inflammatory changes but to disturbances in the venous circulation of the pelvis. These venous changes may produce the same symptoms as adnexal disease.

POINTS IN ANATOMY

The anatomical fact that the pelvic veins are without valves predisposes them to overdistention. At certain vulnerable points, the support of their walls is insecure. This condition is most apparent in the ovarian circulation, less so in that of the uterine venous channels. The ovarian veins and their pampiniform plexuses are supported by a delicate network of intrinsically interwoven strands of elastic fibers and slender, smooth muscle bundles. This support is attached to the peritoneum at one end and the basal ligaments of the pelvic fascia at the other. It is not strong enough to withstand prolonged vascular distention.

The ovarian circulation is more subject to varicosities than the uterine. The veins swing in a sort of peritoneal hammock. Just before they reach the pelvic brim, they are subject to pressure from the sigmoid and cecum. The left ovarian vein terminates in the renal vein, which it joins at right angles without a protecting valve. The right ovarian vein enters the inferior vena cava. Here there is a valve, the only one in the venous circulation of the pelvis. Whenever there is stasis in the ovarian circulation, the long column of venous blood extending from the ovary to the vena cava or left renal vein gravitates to the most dependent portion; namely, the pelvic course of the vein.

Any added strain on the ovarian circulation necessarily aggravates the embarrassment already existing by virtue of anatomical peculiarities of the ovarian veins. Part of the burden of returning venous blood is thrown upon the adjacent peritoneal veins. The resulting pressure soon affects the widely ramifying nerve fibres accompanying the bloodvessels and bearing so intimate a relation to the peritoneum. The pressure on these nerve fibres results in deep seated pain, most commonly located in the ovary; hence the term "ovarian neuralgia." The pain may radiate upward or downward, and the patient may experience a high lumbar backache, a bearing down sensation in the cul de sac, or a dull ache on the posterior surface of the thigh. As soon as pressure is relieved by the recumbent posture, the pain is diminished or disappears.

ETIOLOGICAL FACTORS

Varicosities of the female pelvis are most commonly observed between the ages of the late twenties and the late thirties. Years ago, Skene stated that it occurs more frequently in middle life; he never saw a case in a patient under twenty-five or over sixty. The age incidence suggests that menstruation and parturition are important etiological factors.

I have frequently observed thickenings on pelvic examination, leading to the diagnosis of pelvic cellulitis, which disappeared on the operating table. In parametritis, venous congestion is pronounced. In this common disturbance, a protective exudate is formed. Venous hyperemia is followed by transudation of serum, diapedesis of red blood cells, phagocytic migration of leucocytes, pus elaboration and proliferation of connective tissue cells. These changes take place within the folds of the broad ligament. As the connective tissue organizes and the scar tissue contracts, fibrous bands are formed that interfere with the venous outflow. The result is the formation of varicosities.

In pelvic cellulitis, also, tremendous venous enlargement is found at operation.

Following Dudley, the etiological factors may be divided into two groups; namely, 1, constitutional and 2, mechanical. The various factors under these headings may be classified as follows:

CAUSES OF PELVIC VARICOSITIES

1. *Constitutional.*—a. Subinvolution of the ovarian and uterine vessels, prolonging pelvic engorgement. b. Relaxation of the pelvic tissues, resulting from injury. c. Poor state of general health. d. An unhealthy condition of the venous walls, due to inflammatory changes and aggravated by the anatomical facts of absence of valves in pelvic veins; the result is an increase of the pressure in the pelvic veins when the woman assumes the erect posture.

2. *Mechanical.*—a. The anatomical peculiarities of the ovarian veins; the left, because it empties into the renal vein at right angles and has no valve, is more frequently involved. (In males, varicocele is more common on the left side for the same reason.) b. The great length of the ovarian veins. c. Habitual constipation with intestinal stasis. d. Uterine displacements.

It is generally agreed that pregnancy is the most important factor in the production of varicosities. Faulty involution of the uterus prevents the dependent pelvic circulation from returning to a normal state. After abortion there is likely to be subinvolution, because uterine development has been interrupted in this condition. The pelvic circulation may remain in a state of stasis for a long time, after which permanent distention of the veins may take place.

Next in importance to pregnancy as an etiological factor is uterine displacement. The resulting stasis leads to the formation of a vicious circle; that is, the displacement leads to stasis, which in turn aggravates the pathological condition of the uterus. Consequently, the size and weight of the organ are increased, and hypertrophy and hyperplasia, ultimately fibrosis, take place. This disturbance affects also the cervix uteri and the ovaries. It is usually designated as chronic metritis, cervicitis and oophoritis.

Because of the fact that sclerocystic ovaries are commonly found in association with pelvic varicose veins, the ovaries have for some time been considered the cause. It is true that pelvic symptoms disappear after the removal of such ovaries; this fact, however, does not prove their etiological relation. When the ovaries are removed, the pelvic circulation is necessarily interrupted; therefore relief from the symptoms of pelvic varicosities would be expected, regardless of the origin of these lesions. The relief comes from the destruction of the ovarian veins, not the extirpation of the ovaries. If the varicose veins alone are removed and the ovaries left intact, the reestablishment of venous drainage results in a restoration of normal conditions in these organs.

Emge (2), in a series of one hundred cases of pelvic varicose veins, found many sclerocystic ovaries. When the varicose veins were removed, he found that ovarian function was restored and the pelvic symptoms disappeared.

SYMPTOMATOLOGY

Varicosities in the female pelvis may produce a great variety of symptoms. As the symptoms are likely to vary greatly according to individual cases, it is impossible to give a hard and fast exposition of the symptomatology.

Only in about fifty per cent. of the cases is the diagnosis made. The condition is recognized preoperatively in about twenty-five per cent. of cases, and even then the diagnosis is tentative. In twenty-five per cent. of cases, the diagnosis is made on the operating table when the condition has not previously been suspected.

Pain is the most common symptom. It is located in the extreme lateral portions of the pelvis; it is more common on the left side, presumably because of the anatomical peculiarities of the left ovarian vein and the pressure of the sigmoid. It is constant but indefinite. Exertion, sexual relations, constipation and premenstrual engorgement aggravate the pain. Rest in the recumbent position alleviates it.

Backache is second in importance. The pain is diffuse, present on rising, increasing during the course of the day, and subsiding when the patient rests in the recumbent position. According to the chronicity of the pelvic stasis, the backache progressively increases in severity.

Another important symptom is leucorrhea, which is a manifestation of congestion, not infection.

Ovarian neuralgia is another complaint. Previously in this paper, the anatomical relation of ovary to peritoneum and pampiniform plexus of veins and the mechanism by which venous distention may thus produce pain by pressure on the nerve fibres that accompany the vessels has been pointed out. In cases of ovarian neuralgia, pelvic examination is likely to disclose an enlarged and tender ovary.

Menstrual irregularities and dysmenorrhea appear in cases associated with prolonged pelvic stasis. Sometimes the menstrual cycle occurs at increasingly shorter intervals, and at times the period of flow is prolonged and accompanied by menorrhagia. The cause of the disturbed menstrual cycle is the ovarian congestion, resulting in overstimulation. As a result, there is hyperplasia of the endometrium. Since fibrosis interferes with the maturation of the graafian follicles and also the blood supply of the endometrium, the flow ultimately becomes irregular and scanty.

Many other symptoms may be elicited in the history, including dyspareunia, frequency of urination and leg ache. Frequent urination without nocturia or abnormal urinary findings points to an involvement of the vesical plexus. Leg ache is spoken of as a tired feeling along the backs of the thighs. It is present in advanced pelvic stasis, when there is pressure on the obturator nerve.

POINTS IN EXAMINATION

In examining patients for suspected pelvic varicosities, it is essential to have them assume various positions. In the dorsal position, the distention is relieved and the condition may be easily overlooked if no further examination is made. If palpation is made with the patient in the sitting position, an increased size of the vascular structure of the broad ligament may be noted. It is often difficult to definitely map out a varicocele; but, in many cases, distinct varicosities may be felt.

The color of the vaginal mucosa may give some

information. A bluish, thickened, excessively moist vagina is indicative of pelvic stasis. Vulvar and vaginal varicosities may be observed. Their presence points to the probability of similar lesions within the pelvis. In the early stages of pelvic stasis, the findings in the uterus on palpation suggest early pregnancy; later the uterus becomes large, bulky and hard.

SURGICAL TREATMENT

In most cases of pelvic varicosities, the symptoms can be relieved completely by operative means. Emge (3) cites various authors as having employed the following surgical measures: resection (excision) of veins; multiple ligation of veins; castration; resection and oophorectomy; resection or ligation of veins and ventrofixation; ventrofixation; and shortening of the sacrouterine and round ligaments. Emge believes that, since the fibroelastic suspensorium is intimately attached to the pelvic peritoneum which forms the covering of the basal ligaments of the generative organs, it is possible to obtain a normal control of the veins of these organs by increasing traction on this peritoneum. In his opinion, resection of veins is ordinarily unnecessary and should be confined entirely to varicosities that are the direct result of inflammatory lesions of the vessels in question.

Castano (7, 8) emphasizes the importance of early surgical treatment and employs an operation which aims to divert the blood from the veins in the broad ligament. He exposes the ilioovarian ligaments, brings the varicosed uteroovarian veins into view, ligates them above and below with catgut, and divides each vein between the ligatures. This operation he terms the "Argentine method."

CONCLUSIONS

1. Many obscure gynecological syndromes are due to disturbances of the pelvic circulation, especially varicosities.

2. Various anatomical peculiarities predispose to the development of varicose veins in the pelvis; namely, the length of the ovarian veins, the absence of valves, and the lack of support from the surrounding tissues.

3. The most important causes of pelvic varicosities are pregnancy and uterine displacements. The constitutional etiological factors include subinvolution of the ovarian and uterine vessels, relaxation of the pelvic tissues, poor general health, and an unhealthy condition of the venous walls; the mechanical causes, the anatomical peculiarities of the ovarian veins, their great length, habitual constipation and intestinal stasis, and uterine displacements.

4. The principal symptoms are deepseated pain, backache, leucorrhea, ovarian neuralgia and menstrual irregularities. Less common symptoms are frequent urination, dyspareunia and leg ache.

5. In making the pelvic examination, it is important to place the patient in various positions. If only the dorsal recumbent position is employed, the venous engorgement may subside and the varicosities be overlooked.

6. Complete relief from the symptoms may be expected after surgical correction of the lesions.

Retinitis of Pregnancy

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

The retinitis of pregnancy is far less common than that of albuminuria, the former being met with about once in three thousand pregnancies. It is not more frequent in primiparæ and is more prone to occur during the last three months of gestation, very rarely in the postpartum. Its onset is slow, progressive, while the amaurosis develops very suddenly. Visual acuity diminishes in phases, offering various degrees from simple cloudiness to complete cecity. Early ophthalmoscopic diagnosis is essential in order to begin treatment as soon as possible. As to the objective examination there is the symptomatic trio, namely, papilloretinal edema, hemorrhage, and exudates. Papillary reactions are preserved but may be sluggish. The objective signs dominate the entire clinical picture; the visual disturbances may remain as they were at the beginning and in no way proportionate to the changes in the fundus; they above all depend upon the localization of these changes. A minute macular lesion will attract the patient's attention far more than a pronounced edema or hemorrhage in the neighborhood of the papilla.

It is only exceptionally that a retinitis improves as long as pregnancy continues, even by diet which ameliorates the general condition or prevents the advent of eclampsic crises. Sight continues to decrease or the diminished acuity remains stationary until the day of labor which ends the term of general accidents and those of the eye. Then normal visual acuity will return in a few months, although the prognosis of vision is darkened by the possibility of two complications, viz., atrophy of the optic nerve and detachment of the retina. The latter occurs in seventeen per cent. of the cases; usually it is bilateral, sometimes total,

but usually partial. There is a happy tendency to recovery, but when this takes place the vision is never what it was. Atrophy of the optic nerve develops in thirteen per cent. of cases and may result in cecity.

The prognosis of pure retinitis of gestation is far from having the gravity of that occurring in a pregnant woman with nephritis; nevertheless, it is to be guarded against, both from the vital and visual viewpoints. As to vision, the prognosis depends upon the extent and localization of the retinal lesions, the time of gestation when the ocular disturbances arise, and the rapidity of therapeutic interference. From the vital viewpoint, it must be recalled that death may ensue during eclamptic attacks, and gravidic retinitis is an index of a profound involvement of the organism, announcing the advent of serious accidents if early and active treatment be not resorted to. Another element in the prognosis that must not be overlooked is the possible persistency of nephritis after labor has taken place and also that the retinitis may recur in future pregnancies. The fetal prognosis is absolutely unfavorable, the mortality being about eighty per cent.

Treatment in the first place should be to prevent the accidents by careful supervision of any woman who presents signs—be they ever so slight—of gravidic toxemia, and secondly, to treat the retinitis. It is to be noted that the extent of organic involvement may be made by the ophthalmoscope.

The diagnosis of retinitis having been made, it is to be recalled that the maximum of prognostic gravity resides in the continuation of the pregnancy. It improves with spontaneous miscarriage and is more favorable still when induced miscarriage or premature labor is resorted to. The best vital prognosis can be given when artificial interruption of pregnancy is made. When it is remembered that the life of the offspring is so seriously compromised, it would seem only logical to interrupt the pregnancy as soon as the ophthalmoscopic signs of retinitis are detected.

Clinical Observations with Painless Childbirth by the Synergistic Method

D. DEUTSCHMAN, M.D.

New York

With the rapidly increasing number of neurotic women, as a byproduct of modern civilization, with their extreme sensitiveness to pain and their inability to tolerate physical or mental torture, there has never been a more persistent demand for the elimination or amelioration of the suffering associated with the process of childbirth. This justifiable demand coming from frightened, childbearing womanhood has stimulated the medical profession to the attempt to find a remedy for the production of a normal, physiological, painless course of uterine contractions during the process of labor. From time immemorial medical men have striven to eliminate the pain of childbirth and the achievement of this ideal aim of the pioneers of the profession constitutes a fascinating chapter in the history of modern medicine. Any method advanced for this purpose has always been met in the most enthusiastic manner, demonstrating definitely how anxiously the community is looking forward to the medical profession to facilitate the burden of parturition.

Many methods have been tried from time to time to regulate the pain of childbirth with varying results too often based upon empirical grounds rather than upon scientific facts. The encouraging results frequently obtained by some authorities failed in the hands of others. This failure to give uniform results in the attempts to eliminate the pain of childbirth is due to our lack of knowledge of the basic principle underlying the termination of gestation and the onset of labor. Of the numerous methods for the relief of pain of childbirth that have been advanced within the last decade there were two that have gained the widest interest of the profession as well as that of the laity. Those are the Freiburg method or that of Kronig and Gauss, which is based upon the combined effect of scopolamine and morphine, and the other one is the synergistic method of Gwathmey which is based upon the interaction of magnesium sulphate, quinine and ether.

TWILIGHT SLEEP

The former, which is commonly called twilight sleep, was introduced to the American medical profession, as well as to the laity of this country, on the recommendation of the two above named eminent obstetricians of Freiburg, who asserted that they had good results with the use of their method. How this method was received in this country, especially by the female population, is only a matter of recent history. One still remembers the formation of the numerous women's leagues, the press campaign, the pictures on the screens of the theatres and the daily lectures delivered by honest but incompetent laymen and women at the different department stores, for the purpose of disseminating the knowledge of this method among childbearing women.

This method was given a fair trial for a period lasting several months. But the results following its employment in the various hospitals were so disastrous, by increasing the fetal and maternal mortality that it had to be abandoned. It was almost unanimously pronounced a total therapeutic failure by the most competent and skilful obstetricians of the country, who had faithfully and punctually carried out the technic as described by the authors of this method. There were too many blue babies and too many postpartum hemorrhages. This medical illusion lasted only a comparatively short period and the women were tragically disappointed.

The other method mentioned, i. e., the Gwathmey

method, is based upon the synergistic action of various drugs to effect a form of analgesia without producing anesthesia and without interfering with the normal course of uterine contractions. This method, when properly carried out, tends to shorten the duration of labor by softening the cervix during the process of dilatation and saves the strength of the patient for the stage of expulsion. There are no bad effects on mother or child. The procedure is a comparatively simple one and does not require special skill and can easily be carried out at the hospital or home by any intelligent and patient physician.

The technic as worked out by the New York Lying In Hospital, where this method has been used for the last three years on a few thousands of cases, is as follows: The preliminary preparations consist in gaining the confidence of the patient by pleasantly emphasizing the importance of cooperating in this procedure. The patient receives a high soapsuds enema followed by a rectal irrigation of tepid water, until the return is absolutely clear. She is to be placed in a quiet room and, if no room is to be obtained, the bed should be screened. Her eyes are covered with a piece of cloth and the ears closed with cotton, so as to keep out all the external stimuli.

The active procedure is begun after the patient has advanced in labor to the stage of two and a half or three fingers of cervical dilatation with uterine contractions of six to seven minutes interval and of ten to twelve seconds in duration, when an intramuscular injection of two c. c. of fifty per cent. solution of magnesium sulphate combined with one quarter of a grain of morphine sulphate is administered into the gluteal, intrascapular or deltoid regions. This injection is to be given during one of the uterine contractions, care being taken not to inject the solution in the skin. If this injection produces too sedative an effect, wait until it is worn off before proceeding with the next step. If no effect follows the first injection within twenty minutes, another two c. c. of fifty per cent. magnesium sulphate solution without morphine is to be injected. After the slight drowsiness, which invariably follows the second injection and which is the effect desired, the patient receives a retention enema of a mixture consisting of twenty grains of quinine alkaloid, forty-five minims of alcohol, two and a half ounces of ether and a sufficient quantity of olive oil up to four ounces. Prior to the rectal instillation the rectum should be well lubricated with petrolatum or oil on a gloved finger and the entire anal region including the buttocks and upper parts of the thighs should have sufficient lubrication. The mixture should be warm before pouring it into the apparatus, which consists of a funnel, rubber tubing, glass tube, a Murphy regulator, for regulating the flow of the mixture, and a rectal tube. After the apparatus has been connected together it should be well lubricated with warm oil and the rectal tube inserted slowly, high up in the rectum over the presenting parts, care being taken not to insert the tube during a uterine contraction. The patient is placed on her left side with the hips slightly elevated to promote colonic absorption. After the mixture has been emptied, which should take about ten to fifteen minutes, the rectal tube is gradually withdrawn, instructing the patient to relax during the period of the removal of the tube and gentle pressure over the perineum should be exerted to help the retention of the mixture.

Following the administration of this retention enema the patient usually becomes drowsy, followed by a semistuporous condition, resting peacefully between the uterine contractions and only moaning faintly during the height of pain, the frequency and duration of which is not affected.

The patient is not to be disturbed with examinations for about two or three hours, during which time she should be carefully watched and be prepared for a precipitate delivery, which often happens, due the hastening of the first stage of labor apparently produced by this synergistic method.

If no analgesia follows the administration of the medicated enema mentioned above, a third injection of the two c. c. of fifty per cent. magnesium sulphate may be given within one hour after the rectal instillation, without any toxic effect upon mother or child. This additional injection fortifies the synergistic effect between the magnesium sulphate and ether and the patient is relieved of her pains of the uterine contractions during the stage of dilatation.

When the patient is examined after the rectal instillation the physician cannot help being impressed with the remarkable progress in the process of labor. The cervix is invariably found much thinned out or completely obliterated; the cervical dilatation almost complete and in cases of occipitoposterior, it is found to have undergone spontaneous rotation and the presenting parts frequently found on the perineum ready to be delivered, with the patient being in a state of complete rest and perfect calmness.

The effect of this procedure lasts about four hours, after which period it begins to wear off and, if the patient by this time is not ready for delivery, the whole treatment may be repeated, leaving out the morphine, without jeopardizing the health of mother or baby.

After the first stage has been completed the patient is either allowed to go through the second stage spontaneously, during which course she displays remarkable vigor, strength and energy in utilizing the intra-abdominal muscles in facilitating the expulsion of the baby, or the patient may be assisted by the administration of a little gas and oxygen or ether anesthesia and by the application of low forceps in the delivery of the newborn.

The fifty per cent. magnesium sulphate used in this method is for the purpose of analgesia as well as potentiating the therapeutic action of the ether, which is given in a nontoxic dose absorbed by the colon, without affecting the higher centres. However, I do not intend to delve any further into the merits or therapeutic demerits of the different ingredients employed in this method of treatment, neither do I wish to enter into theoretical details of comparative values of the different processes designed for the purpose of procuring a painless course of labor. I merely intend to report the clinical results and observations from the employment of a method, the principle of which has been worked out and used for the last two or three years at the New York Lying In Hospital, under the leadership of Dr. J. T. Gwathmey, who deserves the credit for attempting to solve the problem of perverted biology of painful parturition, on a rational and scientific basis.

The encouraging results obtained for the last few months from a number of cases in which the technic was properly carried out were uniform and highly satisfactory. I am almost tempted to state they were above expectation. Cases that failed in their results were those in which there had been a faulty technic. To illustrate this point I wish to report a few of my cases:

Case I.—Mrs. F. E., American born woman, twenty-eight years of age, cultured and intelligent; borderline case of contracted pelvis, para two. First baby, nineteen months old, was delivered in an occipitoposterior position after a dry and prolonged course of labor. The delivery was instrumental. She was admitted to the hospital at 10 p. m. Patient under great apprehension, fearing a repetition of the tortures of her previous confinement. She finally decided to have the baby by a Cæsarean section, in order to save the agony of her first experience.

Vaginal examination revealed a thick and long cervix, rigid in consistency; cervical dilatation close to three fingers, during a uterine contraction; membranes ruptured; head presentation, not well engaged in an occipitoposterior position. The condition was similar to that of the first labor. The uterine contractions took place about every six or seven minutes and were about twelve seconds in duration.

After having prepared the patient in the manner described above, which lasted about three quarters of an hour, at 10.45 p. m. she was given two c. c. of fifty per cent. magnesium sulphate with one quarter grain morphine, injected intramuscularly in the gluteal region. There was no visible change observed in the sensitiveness of the uterine contractions within a period of twenty minutes, when another injection of the magnesium sulphate without the morphine was administered. Within the next ten minutes following the second injection there was a marked form of analgesia produced, as was manifested by her attitude during the subsequent uterine pains. At a quarter after eleven p. m. the rectal instillation was administered. The patient became drowsy shortly after, resting peacefully during the periods between the contractions and moaning faintly towards the end of pains, that were unaffected, either in frequency or duration. About 2.30 a. m., i. e., about three hours after the rectal instillation, the patient was examined and the cervix was found completely obliterated, the cervical dilatation was complete and the head on the perineum in anterior position. The baby was delivered with low forceps under a light ether anesthesia, without the slightest effect upon baby or mother. One half hour later, when learning of the birth of the baby, she was the most surprised person living and expressed her deep gratitude for having been saved the pains of labor.

Case II.—Mrs. J. R., twenty-two years of age, born in this country, para one, was admitted to the hospital about 10 p. m., at the same time with the patient mentioned above. Examination revealed a long, thick, rigid cervix, about three fingers dilatation, membranes ruptured, cephalic presentation, slightly engaged in R. O. A. position, with pains every five or six minutes and about fourteen seconds in duration. She was extremely restless and excitable with every uterine contraction and it was impossible to control her paroxysmal attacks of hysterical manifestations. At 11 p. m., after the preliminary preparations, the two c. c. magnesium sulphate with the one quarter grain of morphine was injected intramuscularly. Within ten minutes following the injection there was a noticeable relief of the pains as evidenced by the patient's statement that she was much relieved and also by her changed behavior. At 11.25 p. m. the rectal instillation was administered and shortly after she became drowsy, resting quietly between the frequent and strong uterine contractions and moving and moaning during the pains, in a semi-stuporous condition. At 11:50 p. m., patient became restless and another injection of magnesium sulphate without morphine was injected. Patient immediately fell asleep and rested until 2 a. m., when bulging of the perineum was noticed and, when the patient was examined, she was found ready to be delivered. She walked to the delivery room, where she was prepared and allowed to go through a spontaneous delivery, without anesthesia.

It was remarkable to watch the patient, in a semi-stuporous condition, using the entire strength of her abdominal muscles in bearing down during every uterine contraction. She appeared to be rested and full of energy although in a state of drowsiness.

Shortly after the birth of the baby, which was perfectly normal, patient made the following remark: "The opinion of women that giving birth to a baby is painful is false."

Case III.—Mrs. E. S., young American woman, para two, first delivery was instrumental and prolonged, was examined at 11 a. m. at the hospital. She had a tender perineum, due to retention of a piece of unabsorbed suture material left from a perineorrhaphy of first delivery. The cervix was thick, rigid, long and lacerated. Dilatation about two and a half fingers, membranes ruptured, cephalic presentation, sagittal suture in a transverse direction and the head not well engaged. Patient was having pains every six minutes, about ten seconds in duration. She was extremely irritable, disagreeable in disposition and very much exhausted.

After the usual preparations she was given the two c. c. of fifty per cent magnesium sulphate with one quarter grain of morphine, at noon. Shortly after this injection her restlessness disappeared and an expression of self contentment appeared on her face and she became submissive to the instructions. She was peaceful between the pains and calm during the pains, which, she stated, were very much less intense in character. Twenty minutes following the injection the rectal instillation was administered. The patient became drowsy, asking questions in a whispering tone and receiving the answers and orders in a most thankful and obedient manner. She rested peacefully between the pains and tossed about during the pains, the character of which was not changed, neither in frequency nor in duration.

The patient rested for three hours, when she began to groan and became restless while the bulging at the perineum was observed. She was examined at 3 p. m., when the cervix was found to be fully dilated, the head rotated to anterior position and lying on the perineum, ready to be delivered. She walked over to the delivery room where she was prepared for the delivery. A light ether anesthesia was given. A perineotomy was performed and a piece of silk liga-

ture was removed. The baby was delivered with low forceps and the perineum sutured.

There was a slight delay in the respiration of the baby, although the heart and color of the baby were good. A whiff of carbon dioxide applied to the baby's mouth brought forth the normal cry. There were no complications in mother or baby. One hour later the patient received guests without showing any evidence of the usual postpartum exhaustion.

The physicians present at the hospital admired the tranquillity of the patient during the uterine contractions of the first stage of labor.

Case IV.—I wish to report this case for the purpose of bringing out the negative results, when the proper technic is not carried out. Mrs. L. S., nineteen years of age, born in this country, para one, the youngest of three sisters, has always been the pet of her mother, extremely temperamental and spoiled by parents as well as by her husband. She was admitted to the hospital with three fingers of cervical dilatation, membranes ruptured, head engaged in normal position, and was having pains every five minutes, lasting about fifteen seconds. She was given the two c. c. of fifty per cent. magnesium sulphate with one quarter grain of morphine, producing a mild degree of analgesia. This was followed, shortly after, by the administration of the rectal instillation, which began to take effect, when, contrary to orders, the patient's mother entered the room of the patient in labor and insisted upon conducting a regular conversation with her daughter and embracing and kissing her during every uterine contraction. This maternal sentimentality resulted in the patient's restlessness, becoming worse with subsequent uterine contractions and her actions became uncontrollable toward the end of the first stage. This case illustrates the importance of preserving the proper psychic atmosphere, when using this method for painless deliveries.

Case V.—Mrs. F. M., twenty-two years of age, native American, para one, intelligent but highly neurotic young woman, was examined at the hospital at 1 a. m. Her cervix was thick and long, cervical dilatation about three fingers, when examined during a uterine contraction; head presentation, which was slightly engaged in R. O. P. position. Membranes had ruptured fifteen hours prior to the examination, during which period patient claimed to have had very frequent and strong pains. She was very restless and exhausted. The uterine contractions were about every five minutes and lasted about fifteen seconds. She was despondent, apprehensive and hysterical.

After the regular preparations and assurance of elimination of her pains she was given the regular initial injection of two c. c. of magnesium sulphate with one quarter grain of morphine. This had a remarkable effect upon the patient. She quieted down considerably during the subsequent pains. Twenty minutes after the injection the rectal instillation was administered and the patient shortly after became drowsy, resting quietly between the pains and waking up several times during the height of the uterine contractions. One hour after the rectal instillation the patient received another injection, without morphine, due to restlessness she began to display. The frequency and duration of the uterine contractions were unaffected and the patient rested peacefully for a period of three hours, from the time of the first injection until she was delivered. At 3 a. m. the patient was examined and found ready to be delivered, with the head having spontaneously rotated to the anterior position. She was taken to the delivery room, where she was delivered spontaneously of a seven pound, healthy and normal baby, without any postpartum complications.

Prior to the delivery of the baby a prophylactic episiotomy was performed and the patient did not manifest any sensation of pain. The nurses present at the delivery were much surprised to see me introducing the needles and incising the tissues without hearing any expression of pain coming from the patient's mouth.

Case VI.—The following case illustrates the harmlessness of this method, if a repetition of the procedure should be required. Mrs. M. R., young American woman, twenty-six years of age, para one, highly sentimental and temperamental, of the theatrical type, was examined at the hospital at 11 p. m. and found the cervix thick, long and relatively rigid, with cervical dilatation of one finger and a half. The membranes were intact, pains irregular and not strong. There was head presentation in R. O. P. position, not firmly engaged. Owing to her temperamental condition she insisted upon stopping the pains and, against wishes, I was compelled to administer the treatment, although she was not ready for it. Following the injection of the magnesium sulphate with the morphine and afterwards the rectal instillation, in the routine manner, the patient fell asleep with the uterine contractions completely subsiding, for a period of five hours. She woke up after the five hours of rest and walked around till next afternoon with hardly any pain. At 3 p. m. she was examined and her cervix found to be soft, long and thick. The cervical dilatation was about three fingers, the membranes still intact and the head persisting in the R. O. P. position and more firmly engaged. She was having pains every five minutes, intense in character and about twelve to fifteen seconds in duration. At 3.30 p. m. the repetition of the whole procedure was started and it was completed at 4 p. m. The morphine was omitted. The patient rested quietly for two and a half hours, when bulging of the perineum was observed. When she was examined at 6.30 she was ready to be delivered. The head was found to have rotated to the anterior position. She was given a light ether anesthesia, a prophylactic episiotomy was done and the baby delivered with low instruments. There was no delay in the respiration of the baby, which cried immediately and there was no postpartem complications in the mother. This case shows that when this method is administered too prematurely labor may be delayed for several hours.

SUMMARY

The results obtained in cases selected at random were uniform and highly gratifying. This method was not intended for the purpose of producing an absolutely painless process of labor from the beginning to the end. Neither is it supposed to be a panacea for the relief of all sorts of pain that may incidentally occur during childbirth. When properly carried out this method eliminates the painful sensation associated with the uterine contractions of the greatest part of the first stage of labor and possesses

the following definite advantages: It usually shortens the course of parturition. It frequently corrects malpositions. The technic is comparatively simple and may be carried out at home or at the hospital. It is devoid of any danger either to mother or baby. There are no postpartum hemorrhages or any other complications. It affords the parturient patient a rest of several hours and thus conserves her strength and energy for the process of the second stage.

It is my firm conviction that with further development this method may become the long sought procedure for producing a painless labor in the real sense of the term, i. e., from the beginning of the first stage until the expulsion of the placenta.

Midwifery in the Homes of the People*

ERNEST KAYE LE FLEMING, M.B. Cantab, M.R.C.S.
Dorset, England

To the general practitioner falls the lot of attending maternity cases in the homes of the people, and although many cases are attended by midwives only the general practitioner is sure to be called upon if the case presents difficulties.

Often, and in country districts especially, the conditions under which he has to perform his duty vary from the ideal, which are those which approximate to hospital or nursing home standard, to the other extreme. Every general practitioner of experience could give instances of attending cases of childbirth under conditions which make impossible any approach to ordinary cleanliness, still more to the standard of surgical cleanliness which he desires. The very difficulties, however, he so often encounters, the lack of assistance he can obtain and his wide experience singlehanded, tend to develop his skill, resource and independence, making him, what he so often is, a real specialist in midwifery.

From the general practitioner's point of view midwifery cases are the most trying of his many duties. Apart from the inconvenience of interruption of his routine work at a moment's notice for an indefinite time, coming in the midst or after heavy work and often breaking his night's rest, no case gives more anxiety and worry than a maternity case that develops complications during the puerperium. The sense of personal responsibility is indeed heavy, however much the conditions of labor which favor such complications were beyond his control, and however much the surroundings of the patient tend to retard recovery.

Of these puerperal fever stands conspicuous in the eyes of both doctor and public. Much has been written on the statistics of those cases, and it has been argued that the incidence of this complication should be an index to the advance in the standard of treatment of maternity cases, and that a decline in incidence should appear *pari passu* with increased care, attention and cleanliness in the conduct of labor. Further, that the absence of such decline indicates that the improvement in other aspects of public health is not shared in maternity cases as shown by the maternal death rate. This subject is too large to allow of more than brief reference here, but I should like to take this opportunity of expressing my own dissent from such conclusion.

Apart from the unreliability of figures taken from selected areas of an illdefined condition, the fact remains that a large number of these cases (twenty-five per cent. of published figures) arise when labor has been apparently normal and free from interference by nurse or doctor. Moreover, every doctor knows that cases, where many factors which favor sepsis are present, frequently run a normal course, and that septic symptoms sometimes develop when least expected. It would seem that we must look for some further unknown influence to explain such cases, possibly, for example, an unrecognized influence tending to diminish the normal personal resistance to infection.

This subject leads me to speak of one aspect of the conduct of labor which is of great interest to both public and doctors, namely, the use of instruments in uncomplicated labor. It is argued sometimes that since any interference with the course of labor adds to the risk of sepsis, instrumental aid to delivery should only be used when necessary for the safety of mother or child. In other words, instruments are sometimes used to save time or to satisfy the patient, and that such procedure is unjustifiable. I can only speak for myself in this respect, but I am confident that I have a large body of professional opinion behind me in the view I take on this question.

It is not uncommon for a prospective mother (especially in better class practice), before engaging her medical attendant, to enquire as to his views in this respect and to exact a pledge that she shall be saved unnecessary suffering.

Personally, under proper conditions, I do not hesitate to shorten labor and its attendant suffering in this way when it seems to me advisable, nor do I consider any extra risk is involved. Much depends on the temperament of the mother and her reaction to pain. On the whole the patient of today expects to suffer less pain than she did twenty years ago, and the modern mother expects more help in this respect than used to be the case.

Speaking generally after an experience of twenty-five years in town and country practice, I am convinced that there has been the same steady advance in the treatment of maternity cases as there has been

*Read before the Fourth English Speaking Conference on Maternity and Child Welfare, London, July 5, 1926.

in medicine and surgery generally, and in the public health.

The quickening of means of communication by telephone and motor car brings the doctor, especially in rural districts, nearer to his patient, and renders further assistance more easily obtained. The general standard of cleanliness in the home has advanced and with it facilities for obtaining the necessary supply of clean water, linen, etc. The handy woman is steadily being replaced by the trained midwife. Nursing associations are springing up everywhere. A complicated case is recognized earlier and more easily dealt with. Hospital accommodation for special cases is increasing with the necessary transport arrangements.

It is along these lines that we must look for continued improvement. We need a larger supply of properly trained midwives who can deal with uncomplicated cases and recognize abnormal cases early, and who can educate young mothers along right lines. Antenatal and postnatal clinics must be increased, the former especially to sift out cases of possible pelvic malformation and independent disease with a view to hospital accommodation and treatment.

Facilities of this kind will not only benefit the cases themselves, but will ease the burden of general practitioners in dealing with a branch of his work which in proportion to the skill, time, labor and anxiety expended, bring him a financial return that can only be termed nominal.

Publicity Methods in Maternity and Child Welfare*

LORD RIDDELL
London

Publicity regarding maternity and child welfare work must be popular, attractive and accurate. Highbrow articles are useless for popular purposes and inaccurate material is a positive danger. These may seem truisms. Experts are likely to forget that even the terms they use so glibly are often not understood by ordinary people. "Antenatal," "postnatal" and "neonatal" are good instances. How few people understand the meanings of these phrases! Most writers on health subjects assume that their readers know much more than they do. It is also essential to remember the importance of selecting the right media. When advertisers are about to engage in a campaign, they select publications best calculated to reach the class to which they desire to appeal. Indeed, the selection of media is an art in itself. What applies to advertising applies to health propaganda. We are all prone to attach too much importance to publications which we read and which appeal to us. Although not so spectacular, a suitably written article in what may be regarded as a common publication, read exclusively by women, may be far more effective for this particular propaganda than one in what may be described as a highclass daily newspaper. Unfortunately, most writers like to see their productions in publications that appeal to them rather than those which appeal to the class they wish to reach, when that class does not happen to be of the superior variety. A certain measure of dignity must be preserved, but in making a popular appeal regard should be had to the human touch. A short time ago I equipped a maternity centre in north London. The premises had been used as a public house. I suggested that the centre should be called "The Mother's Arms," but my suggestion was negatived as being too frivolous. Perhaps my critics were right, but as a publicity man I am sure that if the title had been adopted the new clinic would have been a landmark in north London. The work itself, however, is the best advertisement, and we may well be proud of what has been accomplished by the various agencies engaged in dealing with maternity child welfare, and the health of the child at school. It is, however, unfortunate that so little information is supplied to the public as to what is being done by these various agencies. How little the public know about the examination of school children, how the work is done, by whom it is done, and what steps are taken to remedy defects discovered! The same applies to the various clinics, scattered throughout the country. Few people know by whom they have been established, how they are paid for, how they are officered, and how their functions are limited. The public are also profoundly ignorant of the details regarding the midwifery service.

Little is known either about antenatal work. Perhaps from motives of delicacy the subject has received practically no publicity. The importance of improved midwifery and antenatal methods is not realized. Few people understand that this is one of the most important branches of medicine and preventive medicine. It is not understood that there are always approximately three quarters of a million expectant mothers, and that three babies are born every two minutes. Until it is too late most women do not appreciate that their whole lives may be embittered by the results of unskilful treatment or foolishness on their own part. The time has come when this subject should be discussed more freely. The expectant mother and childbirth are usually spoken of as if the subject were taboo. Instead of saying a woman is pregnant, we say she "is in a certain condition." Why should we not be natural in dealing with such matters?

To return to our publicity activities, much would be done if the various authorities engaged in this work were to take steps to acquaint the public with what they are doing. The work goes on from day to day, and most effective it is. But very little is said about it. Good copy is available, and if the authorities were to take suitable steps the newspapers, and in particular local newspapers, would be only too glad to avail themselves of it.

*Address delivered before the Fourth English Speaking Conference on Maternity and Child Welfare, London, July 5, 1926.

Historical Medicine

The Legacy of Greece to Galen

IV. The Failure of Nerve

JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

In notes upon the religion of science I have made of my amateur browsings on the wisdom of Plato and Aristotle I discover I have been thinking of it from a purely materialistic viewpoint without any reference at all to the flocks of gods which hovered over them or demons which bothered Thales before them and even Aristotle to such a degree they had to make place for them. I have clung to the manifestations of the science of religion which is to be thought of in the contact of the finite with the infinite, of materialism with mysticism, of matter merging into spirit —or into energy if you choose and we must be materialistic still. On such borderlines of advanced thought we breathe an atmosphere of adventure and firmness of nerve which invigorates us in a study of Plato and Aristotle. If after getting accustomed to the altitude and breathing freely the reader of science will turn to the philosophical works of Cicero, the *De Natura Deorum,* the *De Finibus,* the *Tusculan Disputations,* etc., he will take note of the change of what in some previous essay I have called the fibre of thought. When I used this term, I remember I hardly knew exactly how to define it or, very likely, exactly what I meant myself, but in reading Gilbert Murray's *Five Stages of Greek Religion,* which in a new edition he has made out of four, I find the strange chapter label, *The Failure of Nerve,* very suggestive. He says he knows no better way of defining that change in religious feeling and theory which ensued on the death of Aristotle. I am sure this observation of the great classicist must be kin to the alteration in the fibre of thought to which I have alluded, but of course he gives to the religious aspect of it a masterly and extended analysis which is beyond my powers and allotted space for the exposition of it in the history of medical science here.

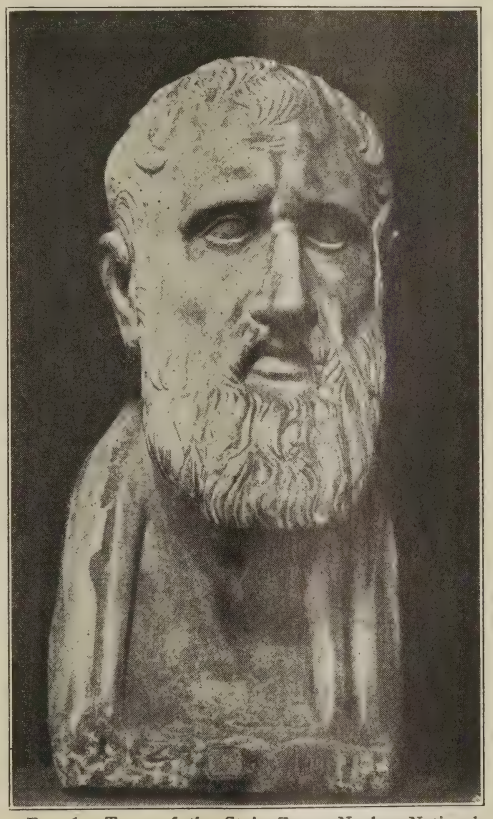

FIG. 1.—Term of the Stoic Zeno. Naples, National Museum. (*After Hekler.*)

Now as we meet with Zeno and Epicurus and Chrysippus, Panaetius and Poseidonius in the pages of Galen we perceive, even forgetting what I have recalled of Cicero and former impressions, that there is a change from the atmosphere of the *Timaeus* and the *de Anima* and the *Metaphysics,* but we naturally ascribe it to Galen's presentation. Galen had no philosophic breadth. He may have been a large fish in shallow waters, but he was no leviathan of the deep.

Yet it is to Galen and his like that we are indebted for the fragments preserved of the philosophers of what we are forced to call the decadence of Greece and involuntarily we say to ourselves, here is the reason. There may have been no sudden change and if we had had their works themselves it might not have been perceptible. Their works perished and Plato's lived. We have the thought of one direct and the others at second hand. This is plausible enough, but if we turn again to Cicero, whose words we have direct, we at least take note that by that time the change is marked indeed. If any one is supreme in the exposition of thought, his own or that of anybody which is not beyond his sphere, if there is any one excels his fellow man in making you forget black is not white, in piling up all the wickedness on one side and all the virtue on the other, he it is. As you read him direct from the standpoint of scientific thought and mindful of that of his own age, you perceive the decadence in the fibre of it—to which I have digressed further than I had intended in beginning a further consideration of how Galen utilized it in his age, decidedly more decadent in intellectual vigor than that of Cicero.

Galen broaches a question (1a) in connection with the circulation of the blood which may well arrest our flagging interest, since he brings into view a very puzzling problem, indeed still a very fundamental consideration in biology. He argues there must be something in common in the nutrition of all parts of an animal, however different in structure those parts may be from one another, which seems true enough. A nerve runs from the base of the skull to the heel, in a sheath no doubt, but nevertheless it or its sheath partakes of a nutrition identical with that through which they have passed. The functions of its branches differ. It is unnecessary to depart from the Galenic conception in details as to this phenomenon.

The modern facts in no way alter the problem of specific adaptation. It was natural for Galen in the light of Aristotle's *Entelecheia* to manufacture a specific one for each locality, but that complicates matters so enormously we are perforce compelled to be satisfied with entelechy in a lump for the whole. It is still simpler to spread it as a veil over all creation. As you pass in your automobile you note the maple tree you saw standing in the beauty of its symmetry a year ago has been riven by a thunder bolt—a section cut out of it, a third of it gone. You feel a pang and pass on. A few years later as you pass you note all its symmetry restored. You can scarcely notice a notch in the outline of the green foliage against the sky. If you are a philosopher of the modern stripe you say the extra nutrition has been diverted to channels necessary to secure again that beautiful symmetry which best adapted it, standing alone and bared to the storms of heaven, to bear the strain and survive. You can say the same thing about the bit of skin you plant or turn inward in a plastic operation on a mucous membrane. Nature might have got along and filled in the gap herself, but she magnanimously accepts your officiousness. You get your bill and a meed of soul comforting praise out of it, but it you stop to think, you are lost. As it is you are more than satisfied, the patient is satisfied and so is everybody else, except Aristotle and Plato. Galen is satisfied that there is a specific power that nourishes the nerve. Plato says it is Necessity and Aristotle says it is *Entelecheia.* You can see these early men say this tentatively, but Galen is satisfied. It is the function makes the part and he writes a famous book on the *Utility of the Parts,* declaring he is moved to choose the title following Aristotle *On the Parts of Animals* but you will take note that Aristotle doesn't give prominence to the Entelechy or the Necessity in his title. That's the difference between Galen and Aristotle and it is a very large one. In a double sense there is a failure about that nerve of Galen's which no one has remedied since. The modern commentator is willing to let Aristotle name it, or the vitalist or the fundamentalist. If he has any preference it is for the modern philosopher who calls it *Evolution or Heredity* even. They can all go back to Aristotle's *Unmoved Mover* and it will not trouble the modern agnostic any more though it becomes even more vague, but we must have names.

Vague as they are, many of them have underlying shades of difference in meaning vastly helpful in analysis. Evolution has given a new meaning to teleology, though the increasing tendency in philosophy to give it a connotation simply with change has largely emasculated it. Aristotle, followed by Galen who carried it much further, built on the basis of Nature doing nothing in vain and that sort of thinking quite aside from the kernel of truth in it has a paralyzing effect on thought and it had its share in paralyzing the legacy of Greece after Galen, but he had the thought as a part of the legacy. Yet for a time it was of great help to anatomy. That function explains and marks out the limit of structure is still a working hypothesis. It was by this means largely that Galen followed the origin, course and distribution of the spinal nerves. It was somewhat due to this he was able to distinguish the sheath of the nerve from its neural contents and prove that the leptomeninges gave origin to the one and the cerebral substance to the other. It helped him and perhaps Herophilus before him to prove the sheaths of the arteries were not at their terminations continued as nerves. Aristotle entertained this idea so far as he seems to have had any conceptions of the nerves. Galen knew, too, but probably from observation, of the central canal in the nerves. Erasistratus at first thought the nerve substance came from the meninges, too (1b), but later with more experience in dissection he also recognized the cerebral origin of the nerves. There were those, as has been noted, who believed the meninges were continued as a fibrous sheet to the membranes of the heart.

While there is no direct acknowledgment of Galen's having dissected the human body, there are intimations of it aside from the dubious references to the body of a robber and bodies of enemies in war. There is no probability at all that he did not dissect the human body at Alexandria, though some of his mistakes in anatomy have been traced to his study of it in apes. He was there in the second century A.D. and he cites from the account of Erasistratus writing in the third century B.C. that the human brain is bilobed in the same way as in animals, so of the ventricles and cerebellum and the convolutions in man, as by far the most intelligent, are the most marked. At any rate it is evident that if Galen himself never dissected man a part of the legacy of anatomy from Greece was derived from the dissection of the human cadaver by a Greek at Alexandria four hundred years before him. If one likes any one can believe there was no dissection of man's body before the Italian anatomists. In Greece it probably was against the law or so dreadful a law was not thought necessary, at any rate it was hidden from the people, but so was body snatching in many states in this country well within the memory of comparatively young medical men. So far as I have observed it is still not one of the features of the Sunday papers to tell the people how and where bodies are procured for dissection. They were probably vastly more chary about its not getting on the first sheet in the Alexandria daily news. Galen disputed the authority of Aristotle who lived four hundred years before him at least and whom he knew as the man best acquainted with the anatomy of apes and deer and hares, but not sufficiently acquainted with that of man. Galen therefore did not feel abashed to point out that Aristotle did not know that man had a deeper furrowed and a more convoluted brain than an ape. How did Galen know?

It was modest in him to say so little against and to say so much for Plato's tripartite soul, but he did not spare Chrysippus for advancing as anatomical proof the story of Athena, the goddess of wisdom, springing from the head of Zeus or of the vulture tearing at the liver of the Titan because of his lust for Hera. Galen, however, missed the historical interest there is in tracing the primitive thought of man through the mind of the greatest thinker of Greece and of his degenerate followers to the well springs of his own thought. These guided Galen and those before him to a correct understanding of the anatomy and physiology of the brain. He was the first great man of experimental research, but folk lore as well

as teleological theory were his guides. The Physician of Cos did not let his theories or idle talk interfere with his common sense and Galen sometimes did. He believed spitting on the head of a scorpion killed it (1c), nay he said he had spit on the head of one himself and killed it. There may be some connoisseurs of slang will think that such lying gives no indication of a failure of nerve, but I claim it shows a decline in the strength of the fibre of thought to go such lengths as Galen did with his teleology and his humoral doctrines. In medicine he was an example of the same perversion of thought of Aristotle as he charges on Chrysippus and Epicurus and the later Stoics. He had not heired enough of the *Sophrosyne* of Greece in his legacy to protect him from extravagances of thought and intemperance of language which Hippocrates evaded. He heired the teleology of Aristotle and the mythology of Plato, but he carried them to excess. It is difficult for modern materialism to understand how men who had so largely abandoned the anthropomorphic idea of God could have gone so far in teleology as Aristotle and Galen. That seems only possible in those who attribute anthropoid tastes and opinions as to what is good and bad in their own conceptions to an allwise Creator and an allprovident Nature.

False as we are disposed to regard it, whether we are modern mystics or materialists, it is erroneous to think this sort of teleology played no beneficial rôle in the achievements of human thought. There is a certain blindness in men which hides the fact from them that the progress of the world has usually been guided by imperfect theory and absurd beliefs. Even the Unmoved Mover of Aristotle we find acting on Aristotle's idea of what is best, but Galen makes the Almighty play some sorry tricks in his philosophy and a good many of them. We are tempted at every turn in his *Utility of the Parts* to abandon physiology for teleology. Indeed physiology was Galen's theology. The works of Nature were the works of God in detail as well as in the plan for the whole and he knew a hundred times more about the latter in the systemic phenomena of animals, or at least of man, than either Plato or Aristotle. The latter had God give a deer huge antlers for defence and swiftness of foot, too, but we are tripped up by a commentator who has the curiosity to know how it was arranged that the heavy horns did not handicap the deer in the use of his swiftness of flight. This is an exceptional slip for Aristotle, but the teleology of Galen is frequently in trouble. Modern physiology is still occasionally absorbed in the *why* rather than the *how* of physiology in discoursing on the functions of the anatomy of life, so perhaps it is not well to cast too many stones or too often at Galen. It is singular, though, as I have before remarked, that of the philosophers it is Plato comes in for most of his praise and not Aristotle. He is the philosopher as well as the biologist and, of all things, the man who taught him that "Nature does nothing in vain," whom the author of the *Utility of the Parts,* takes most to task.

"What could Aristotle have meant by saying the heart is full of nerves? For he is no fake philosopher nor of all things so unskilled in dissection that anyone should think he would slip, like the disciples of Chrysippus, into false ways" (1d). He intimates that students are misled by the careless way Aristotle has written about many matters, because they do not wait for dissections to clear away the difficulties. He accuses Aristotle of careless writing, which anyone reading him may well believe is justified. Aristotle does very frequently, I think his editors agree, slip into ambiguity and inconsistency on account of it, but if the reader, too, gets careless because his mind wanders on account of it, he is apt to miss something new. That danger is not so pressing with Galen. As for the latter's charge, like most progressive men Aristotle is inconsistent at times and often contradicts himself. It is only stagnant men that are not, only narrow men who seek to avoid it.

Toothache Three and a Half Centuries Ago*

THE HONORABLE WILLIAM RENWICK RIDDELL, LL.D., F.R.H.S., &c.
Toronto

(*Concluded from page* 361)

Now, however, we should write on foramina in the teeth or those which are livid when this is caused by influx.

"If the malady does not yield to treatment and the pain continues, the tooth is to be extracted particularly, if it is livid or perforated or loose—either with the instrument or by medicament. A corroded tooth should also be extracted. If, however, it is not corroded or moveable, but is still painful, it should be dried up by actual cautery. These directions are gathered from Galen, Paulus (Aegineta), Aetius and others; but the following treatment is that of the more modern practitioners.

"If the pain arises from humors, mixed with blood, the bile if present, being first purged, the mouth is washed with vinegar in which have been decocted myrtle leaves or oak galls. In the case of extreme pain keeping the patient awake, a dram of theriaca or philonium dissolved in white wine is to be held in the mouth toward the affected part or the vapor from hyoscyamus seed in hot vinegar taken into the

*Written for the Academy of Dentistry of Toronto.

mouth by a funnel. Plasters made of pitch alone or of a mixture of mastich and gum Arabic are to be applied to the side affected . . . thus the flow of the humors is checked.

"After the body including the head is purged where the cause is frigid, pyrethrum is to be chewed, this draws away the pain. . . . Calefacients are to be injected into the ear on the side affected, such as the juice of onions, rue, or matricaria, or some calefacient oil such as oil of almonds, sweet root, lilies, sambucus, in which intestinal worms have been decocted, or of laurel or costus. Fumigation of any hot substance taken through a funnel allays the pain as for example from a decoction of satureia. If there are worms present, something bitter should be added so as to kill them and the teeth should be rubbed with theriaca."

It is seldom that teeth ache unless they are corroded and the corrosion penetrates to the internal cavity, and touches the nerve—and consequently it follows that the maxillaries ache most of all.

In these the cavity is to be filled with aqua fortis. The hollow of the tooth may be filled with mastich chewed and made soft rather than with wax. Afterwards desiccants are to be used lest the applications which clean the teeth should erode them by their acrimony. If there be fetor, musk is to be added, if putrefection, myrrh—at all events if these patients are subject to headache or vertigo because they are injured by the odors. The external parts of the face are to be anointed with anise oil. It is well, too, to draw the humors outward so as to have no repletion. When they go outward, the toothache ceases for a time, the face being inflamed.

The body being purged by pills, we wash the teeth with the sharpest vinegar in which cypress fruit and alum have been decocted. The best prescription is as follows: Take of pepper and pyrethrum each half a dram, of theriaca two drams, mix in the form of small pastilles, one of which apply to the aching tooth.

Hot linen is to be applied frequently to the aching jaw or little sacks of the leaves of amaracum, betonica, or cypress which are applied hot after being sprinkled with white wine. Brandy may be held in the mouth or applied with cotton to the part affected. Oil extracted by distillation from caryophylli is useful —they call it Quintessence—so too the chemical oil of sage or rosemary.

When the gums are swollen, a plump fig split may be usefully exhibited.

In the warmer fluxion, trochees may be prepared from the seed of hyoscyamus, milk, mastich, crocus, in conserve of roses which may be applied to the part affected. Some even add opium in excessive pain. Anodyne cataplasms are used in great pain, made of bread crumbs with oil of roses, etc., or of the pulp of plums cooked under ashes and mixed with a little water to which may be added mucilage of the seed or root of althaea.

If there is caries of the tooth, the blackened and eroded part must be shaved away lest the sound part and the adjoining teeth be infected.

Insensitiveness (stupor) of the teeth is cured by portulacca or oil from immature olives or amurca cooked in a brazen vessel until it has the consistence of honey and used as a unguent.

GLOSSARY

Aizoon minus is the stonecrop, *Sedum album* (the Aizoon majus was houseleek, *Sempervivens Tectorum:* the stonecrop was also called *Sempervivens minor).*

Alica, properly speaking, is spelt, *Triticum spelta:* but as the grain was often used to make tisanes, the word was extended to the tisane itself. It is so employed by Celsus, Pliny and Martial. The epigrammatist says: *Nos alicam, mulsim poterit tibi mittere dives; Si tibi nuluerit mittere dives, eme.* Epig. xiii, 6. We send you barley water, a rich man may send you hydromel: if the rich man don't want to send it to you, buy it yourself.

Altercum, hyoscyamus. Pliny, *Nat. Hist.* 25, 4, 17, says that altercum is the Arabic name for what the Greeks call hyoscyamus (hogbean)—in Latin *Suis faba* or *Faba porcina.*

Althaea, marshmallow: *Althaea officinalis.*

Amaracum, marjoram: *Origanum majoram.*

Amurca, the watery part which flows out in pressing olives, the scum or dregs of oil.

Amylum, starch. Pliny, *Nat. Hist.,* 18, 7, 17, says that is made from all kinds of *triticum* and *siligo* (spring and fall wheat); the best from *Triticum trimestre,* a wheat that ripens in three months.

Asses' milk, lac asininum, used in pulmonary affections.

Astringentia, astringents, medicines which were believed to constringe the organic textures of membranes—such as mint, millefoil, certain nuts and berries. External astringents were often called styptics.

Balaustia, flowers of the pomegranate, *Punica Granatum,* especially of the greater Wild pomegranate, *Malus Punica sylvestris major* were used largely in diarrheas, &c.

Betonica, wood betony, *Betonica officinalis,* of old a great "dryer," vulnerary, diuretic, cephalic and ecbolic—it is, however, in fact, almost inert.

Calamintha, calamint or calaminth, of old a diuretic, emmenagogue, ecbolic, alexipharmic—a whole genus of the *Labiatæ,* now generally called *Clinopodium,* basil.

Calefacients, heating medicines, like mustard and pepper.

Capparis, Capers, prickly caper bush: *Capparis spinosa*—the buds are the well known condiment—the bark, "cortex," was also used as an astringent, diuretic and alterative.

Caryophillus, cloves.

Castoreum, castor, from the beaver, an antispasmodic, nervine, sedative.

Chemical medicines were those obtained by chemical means, fire, &c., on the system of Paracelsus, as distinguished from Galenical medicines, generally "simples."

Conserva rosarum generally of red May and June roses. This conserve was in high repute for pulmonary troubles, especially hemoptysis.

Cornu cervium, deer's horn, shavings boiled in water or wine were considered emollient and nutritious.

Costus applied to several plants oriental and aromatic—chiefly the *Costus aromaticus* (or *Arabicus*), tonic, diuretic, carminative, emmenagogue, &c.

Crocus, saffron, stimulant, diaphoretic, emmenagogue.

Cypressus the ordinary cypress. *Cypressus sempervirens,* berries, leaves and wood are all astringent.

Cypress fruit, berries of cypress.

Cytinus sometimes the calyx of the pomegranate blossom (*Balaustion*): sometimes the *Asarum hypocistis.*

Diamoron, a syrup prepared from honey and mulberries, (Mori) used generally as a gargle: sometimes blackberries were substituted for mulberries.

Dictmnus, fraxinella or origanum, a nervine, anthelmintic and emmenagogue. The species generally employed was *Origanum Dictamnus.* Dittany of Crete—almost inert. Pliny, *Nat. Hist.,* 8, 27, 41, tells an extraordinary story of this plant *"Dictamnum herbam* extrahendis sagittis cervi monstravere, percusi eo telo, pastuque ejus herbae, ejecto." The deers showed the plant dictamnus efficacious for extracting arrows, struck by a missile it was ejected when they ate of this herb. Aristotle says wild goats do this, not deers.

Discutients, medicines reducing humors or all swellings—the word was sometimes applied to carminatives.

Foenugraecum, fenugreek, *Trigonella fœnum.*

Galla, oak galls.

Halicacabus, a kind of bladderwort, *Vesicaria* or *Physalis,* called also Morion, Moly, &c., Pliny, *Nat. Hist.,* 21, 31, 105, says it produces death more quickly than opium, but *"præsentaneum remedium ad dentium mobiles firmandos si colluerentur halicacabo in vino."* a rapid remedy for making loose teeth firm if they are washed by halicacabus in wine. He also

says that skilled soothsayers drink an infusion of the root. Its only known quality is diuretic.

Humor: The physiology and medicine generally of the Middle Ages cannot be understood without the theory of humors. There were supposed to be four humors or fluids of the body—sanguis (blood), chole (bile or yellow bile), phelgma (rheuma or pituita) and a mythical melancholy (black bile). On the proper mixture of these health depended: if any were in excess "distemper" "intemperis" followed—"temperies," temper, really means a due mixture of humors, blood and yellow bile being hot, the others cold.

While most physicians until almost modern times considered that there were four temperamenta, i. e., four forms of undue mixture of humors by an excess of either sanguis, phlegma (rheuma, pituita), bilis (chole) or melancholia, giving to the subject the sanguine, phlegmatic, bilious or melancholic temperament, respectively, there were many whose opinions varied from those of the majority.

For example, the celebrated Dr. Archibald Pitcairne, the teacher of Mead and Boerhaave, in his Latin work *Elementa Medicinae Physico-Mathematica* . . . London, 1717, does not admit of a sanguine temperament at all. In his *Propositiones* as well in the body of the work he makes the Temperamenta three in number. I translate extracts from the *Propositiones:*

"LXV. There are three general temperaments.

YXVI. That fluxility of the blood which (given the impetus of circulation) permits that the Bile is secreted in greater proportion to the other secretions than is usual in most of the inhabitants of the same region exhibits itself in the bilious temperament.

LXVII. That fluxility of the blood which (the spleen being properly constituted) permits that the proportion of the secretions by the kidneys and sudoriferous vascula to the other secretions is too great exhibits itself in the melancholic temperament.

LXVIII. The Pituitous Temperament is where by reason of the force given to the blood by the heart the proportion of saliva to the other secretions is too great."

He adds that anyone who has any of the Temperaments has disease nascent in him.

In the Text, Lib. I, cap. III, sec. 6, he says that it is an error to make four temperaments and that what is called the sanguineous temperament is in reality *plethora;* that temperament comes from the fluxilitas, not the quantity of blood.

Hyssop, *Hyssopus officinalis,* an aromatic stimulant used in an infusion.

Licorice glycyrrhiza, sweet root, *radix dulcis.*

Malicorium, pomegranate rind.

Maticaria, feverfew, pythenium, tonic, stomachic, emmenagogue, anthelmintic, diuretic, &c.

Melilotus, *Trifolium melilotus,* melilot, a kind of clover.

Myrrha troglodytica, myrrh, supposed to come from the land, of the troglodytes who lived in caves—probably from Arabia Felix. But see Pliny, *Nat. Hist.,* 6, 29, 33, 34.

Nymphaea, the common white Pond Lily, *Nymphaea odorata* and *Nymphaea tuberosa.*

Oleum anethinum, oil of dill or anise.

Oleum chamaemelinum, oil of camomile.

Oleum irinum, oil of violets (chiefly the Florentine violet).

Oleum myrteum, oil of myrtle.

Oleum rosaceum, oil of roses.

Oleum rutaceum, oil of rue.

Olivæ omphaticides, olives falling before they are ripe.

Origanum, wild marjoram, has a pungent oil exhibited in toothache. Dr. John Quincy in his *Complete English Dispensatory,* London, 1749, at p. (157) says: "It is a mighty thing with some people for the toothache; they holding it upon some lint or cloth in the mouth as near the part in pain as they can."

Papaver, pepper.

Pentaphyllum, cinquefoil, *Potentilla reptans.*

Perdicium, pellitory, *Xanthoxylum fraxineum,* Pliny, *Nat. Hist.* 22, 17, 19, calls it also parthenium helxine, and sideritis, and says that it has the name, perdicium, because the partridges (pedices) like to eat it—he advised it for gout.

Petroselinum, *Apium petroselinum,* rock parsley.

Philonium or philonanum antidotum, a celebrated eye salve invented by Philo.

Piceae, the different kinds of pitch.

Pimpinella of many kinds, here the *Sanguisorba* which, says Quinsy, *op. cit.,* p. 87, "takes freckles off the face, eases the toothache and ripens swellings. But notwithstanding these wondrous virtues . . . it is now (1749) almost out of practice and is in no great esteem." *Sic transit gloria.*

Polium, poley, Germander, *Teucrium polium,* a strong smelling plant. Pliny, *Nat. Hist.,* 21, 7, 21, says that some call it Teuthrion, that Musaeus and Hesiod praise it extravagantly as good for everything (ad omnia utilem) and the common (but baseless) idea was that its leaves were white in the morning, purple at noon and blue at sunset.

Portulaca, purslane, antiseptic and aperient; According to Quincy, *op. cit.,* p. 198, "a great assuager of choleric heat" and good for the scurvy.

Posca, a drink of mingled vinegar and water; oxycrate.

Ptisanes, tisanes, aqueous medicines like barley water.

Pulegium, *Mentha pulegium,* pennyroyal, fleawort, aperitive discutient, carminative, emmenagogue, ecbolic, etc.

Repellents, medicines for reducing a humor, &c., by driving out the fluid. See Quincy, *op. cit.,* pp. 201, 202.

Repressives medicines to prevent or cure a tumor, &c.

Rubus, berries of the raspberry kind.

Rumex, a dock or sorrel, R. sylvaticus, woodsorrel.

Rumex, a dock or sorrel, R. sylvaticus, woodsorrel.

Ruta, rue. Salvia, sage. Sambucus, elder.

Sapa, a rob of grape must or new wine boiled thicker when not so thick, it was called defrutum.

Satureia, summer savory, *Satureia sativa.*

Senecta, the slough or castoff skin of a snake.

Sweetroot, licorice.

Taeda, tar of various kinds.

Theriaca, a medicine of many ingredients good for everything, preventing and curing—a mithridate.

Veratrum *album,* white hellebore.

Veratrum *niger,* black hellebore.

Vermes terreni, earthworms as distinguished from lumbrici, intestinal medicine. Viola, violet, pansy or flag.

GENERAL NOTE

It may be of interest to add here some medicines approved by another physician—not of so much note, indeed, as Piso or Boerhaave, but still of considerable fame in England in his time. Thomas Fuller, M.D., Cantab. (for whose other book, see Bass' *History of Medicine, Am.* ed., p. 805, n. 1) published his *Pharmacopeia Extemporanea or a Body of Medicines* . . . first, in Latin (five English and two Dutch editions) and then in English—the second edition in English published at London, 1714, is much the best and is that I quote from.

For odontalgia he has many medicines—Electuarium Apophlegmaticum, Epithem Aluminous, Errhines of various kinds, Gargle of Pellitory and other Gargles, Masticatories, Pellets, Epispastic Plaister, and several other Plaisters, Dentalgic Powder, Odontalgic Tincture, &c.

It will be sufficient to give the prescription for a few:

"Aluminous Epithem—Take burnt Allum Powder'd half an Ounce, Nutmeg 1 Dram; Honey of Roses, as much as sufficient to make it of the Consistence of an Ointment, which spread upon Paper, and bind upon that side of the Face that is in Pain, with a convenient Cloth.

"The Toothache is entitled to it, and it hath place when the Cause is not a hollow, rotten Tooth but a sharp Rheum affecting the whole jaw, and one Side of the Face, which bringeth a conflux of Humours and an Inflammation For: it repells very powerfully."

If the pain came from a hollow tooth, he recommends:

"Pellets for the Teeth, Take Asa Foetida, 8 Grams, Camphire, Dragon's Blood, each 1 Grain, Oil of Pepper, 2 Drops, mix. It's to stop a hollow Tooth: "Twill oftentimes ease the most Sharp Pains and prevent their Return."

We end with: "Odontalgic Tincture: Take Roots of Pellitory of Spain half an Ounce; Tobacco cut and dried, Balaustines, of each 1 Dram; Cloves a Dram and a half; black Pepper 1 scruple; Camphire half a Scruple; Hungary Water 8 Ounces; sharp Vinegar 2 Ounces; extract a Tincture; to which (when filtred) add Liquid Laudanum (not tartariz'd) 2 Drams. It may be used with a Decoction of Savine. Let Patient be careful not to swallow it down."

In a small quarto published in London in 1627: *A Thousand Notable Things of Sundrie Sorts,* are to be found very many receipts and nostrums. The author, Thomas Lupton, tells us how to stop an "aking tooth"—he recommends "a certaine woorme with many feet (of some called a swyne louse) to be pricked with a needle and the tooth touched with the same needle; the payne thereof will cease immediately. This I got hardly out of an old booke."

Editorial Articles

HUMAN TYPES

R. B. Bean, of the School of Anatomy, University of Virginia, has made a study of human anatomical types, measuring some thirty thousand American whites and negroes, Filipinos, Japanese, Chinese, Spaniards, and others. He concludes that there are three morphological types which he terms hypermorph, mesomorph, and hypomorph. White persons are only of the first two types. The hypermorphs are tall but with low sitting height, long and narrow arms and legs, slender body, narrow nose, shoulders, thorax and hips. The mesomorphs are of medium stature, broader and bulkier in special features. The descriptions fit only typical subjects, there being various "blends, mixtures, and mosaics."

Bean points out that there is nothing new in this classification and that for mesomorphic other names have been used, as broadback, transverse, lateral, herbivorous, digestive pykniker, muscular, apoplectic, plethoric, phlegmatic, lymphatic: and for hypermorph—narrow back, linear, leptoprosonic, carniverous, sanguine, respiratory, cerebral, nervous, phthisic, cachectic, choleric. Bean thinks that the classification into sanguine, choleric, phlegmatic, and melancholic, attributed to the Greeks, may have been based on four types existant at that time, the sanguine (hypermorph) and phlegmatic (mesomorph) alone surviving in northern climes.

These two types have, of course, been accounted for by endocrine methods. More mesomorphs are found inland and, hence, deficiency of iodine must, or at least may (according to Stockard), be the cause. A more plausible explanation, however, is that of differing food habits.

Draper has recently classified gallbladder, ulcer, pernicious anemia, and tuberculous patients by anthropometric characters, and found the gallbladder and anemia patients were largely of the mesomorph or broad, stocky, type, while the tuberculous and those possessing gastric ulcers were of the hypermorph or slender type. One must wonder as to the relation in these types of cause to effect, of disease to structure, as well as of structure to disease. Certainly one type often changes, at least in part, from one to the other, the slender consumptive of the early twenties becoming the apoplectic person of the fifties or sixties. We can, of course, invoke the aid of endocrine philosophy again, and this has been done to account for the thin, wiry youth, Napoleon Bonaparte, becoming the phlegmatic and obese gentleman of middle age—Emperor Napoleon.

Bean concludes: "From previous studies it was shown that the epitheliopath represents the abnormal hypermorph and is susceptible to disease of the structures derived from the embryonic ectoderm and entoderm, such as the skin, nervous system, and alimentary canal. They are also susceptible to chronic diseases such as tuberculosis of the lungs, cancer, pellagra, leprosy and other diseases of malnutrition. The mesodermopath represents the abnormal mesomorph and is susceptible to diseases of the tissues derived from embryonic mesoderm, such as heart and kidneys, arteries and veins, joints and muscles. They are susceptible to such acute diseases as pneumonia and typhoid fever. There is a question as to whether there are functional epitheliopaths and mesodermopaths or not. There may be changes in the soft tissues during the life of a person so that the diathesis may become, for instance, either plethoric or phthisic. The plethoric may resemble the mesomorph; and the phthisic, the hypermorph." All of which generalizations may contain a grain of truth of some small value to the clinician.

THE IMPORTANCE OF MIDWIFERY

Nowadays, midwifery is looked upon as a much more serious medical or rather surgical event than was formerly the case. It used to be regarded as quite an ordinary domestic occurrence, attended with very few risks, as, in fact, it seems to be at the present time among hardy primitive people. But civilization has altered conditions and changed our conceptions as to the delivery of a woman, or, at least our views on the question have changed more or less recently. Perhaps a somewhat exaggerated view of the risks of midwifery are held by some authorities who think that the management of a confinement is a serious surgical operation which should seldom if ever be allowed to take place in the home. Dr. T. Watts Eden, consulting obstetrical physician, Charing Cross Hospital, in a paper read before the Fourth English-Speaking Conference on Maternity and Child Welfare held in London on July 7, 1926, in reviewing the subject from the consultant's attitude pointed out that the truth lies somewhere between the extreme views that prevail on any subject, and he endeavored in his paper to state where in his opinion the truth did lie.

From the point of view then of the doctor and nurse the conduct of labor was a surgical procedure which might be of the simplest surgical character or it might be attended with developments which at once

transformed it into a major surgical operation. As a rule the possibility of such developments could be foretold during pregnancy, and measures taken either to avert them or to deal with them adequately if they proved unavoidable. This was not true, however, of all the obstetrical complications; there were some which appeared like a bolt from the blue without any previous warning. This element of uncertainty was obviously not without a bearing upon the question of midwifery in the home. It followed that there were certain surgical requirements which must be regarded as the minimum of safety if a woman was to be confined at home. The first was that she should have a room to herself. If the house did not allow of the provision of a room apart that home was unsuitable for confinement and the patient should go to a hospital given adequate and proper simple home conditions and surgical requirements.

Dr. Watts Eden was of the opinion that a woman might safely have her baby at home. That it was safe had been shown by the statistics of the outdoor services of British hospitals, which showed, speaking generally, a child birth mortality rate which was well below the average for the whole country. The incidence of puerperal fever was actually less among the women attended at home in the outdoor service, than in those confined in hospitals. The natural instinct of the female animal to retreat to its lair for the arrival of its young need not, in the opinion of the speaker, be regarded in the case of women, as an atavistic impulse which ought to be repressed.

Dr. Eden holds then that the public attitude, at any rate in Great Britain, has tended to become a little unfair to doctors, and especially to the family doctor, so far as the management of midwifery is concerned. It is pointed out that not all the emergencies of a confinement are capable of being foretold by the most careful medical supervision; that childbirth is inseparable from a certain amount of risk to life, both to the mother's life and to that of the infant; and that assuming an adequate degree of care and skill on the part of the doctor and nurse, they are no more to be held blameworthy for the casualties of midwifery than they would be for the unfavorable termination of a medical or surgical illness. Neither does he deem that the public has the right to demand of a family doctor that he be able to bring to a midwifery case the same high degree of experience and technical knowledge which are looked for in a consultant.

It is futile to think that there will be in Great Britain a hospital bed for every woman in labor, which is the dream of the idealists. Moreover, although the bulk of confinements will no doubt continue to take place in the homes of the patients, Dr. Eden thinks that this can be done with safety if adequate precautions are taken.

Midwifery in this country as well as in other lands takes a greater toll by far than is necessary. Also owing to lack of antenatal care and the want of proper management during labor and insanitary conditions of the home, not only do an undue number of fatalities happen but many women are rendered invalids for life. These facts appear to be agreed upon generally and so impressed are the British Ministry of Health with the unsatisfactory situation in this respect that memoranda have been devoted to the subject in which some of the more obvious drawbacks have been detailed and remedies suggested. Of course, it is beyond the range of human endeavor to provide at once maternity homes or hospitals for all obstetrical cases or even for a large proportion of them, but the more there are the better it will be for the woman in labor. It is said that the training of the medical student in obstetrics and gynecology is inadequate, and that the course in this important branch of medicine and surgery should be longer and more carefully taught and supervised. Proper antenatal care is a long step in the right direction and it is encouraging to know that this precautionary measure is proceeding apace. The subject of midwifery has been neglected and it is well that the limelight of publicity should be thrown upon it. It may be said that this country leads the world in the number of its maternity and lying in homes and in the facilities generally for providing for the skilful care of the lying in woman.

ORPHANS

A revival last spring of *The Two Orphans,* a play which in the early 80's of the past century held the interest of record breaking throngs for many years, passed its way with a bare notice. The piteous scenes which brought sincere tears to eyes of persons half a century ago no longer carried their effect with our audiences of today, largely because the two orphans, with their trials and tribulations, must have seemed almost grotesquely unreal. We do not know the abused, underfed, exploited orphan of fifty years ago, who has vanished with *Tom the Bootblack* and *Phil the Fiddler* and other pathetic waifs of the Horatio Alger period. Even the "poor little orphans" of the asylum of twenty-five years ago, dressed somberly alike in cheap calico who were paraded through Main Street now and then to the interested awe of gaping bystanders, are already becoming a shadowy memory. And the time has come when many of the most experienced experts in this field believe that the orphan asylum—as such—is doomed. At least it is a fact that less orphans are coming, year by year, to asylums. Indeed there seem happily to be fewer and fewer orphans each year in the community.

The reason why the orphan asylum population is decreasing is due in part to the growing tendency to board out children who have been bereft of parents for one reason or another, in carefully selected and officially supervised families. This method is cheaper for the institution, as well as preferable to the average child, for a stigma attaches to the orphan asylum, less, to be sure, than that associated with insane asylums or prisons and correctional institutions, but sufficient to make the normal boy or girl welcome the opportunity to live outside of the asylum building, to attend the local school, to participate in the joys and strifes of the ordinary household life of the foster family.

The causes contributing to the decrease in orphans as a whole are numerous; among the most prominent being the increased longevity of the average man and woman, to whose life modern science has added on an average of five to ten years—just long enough to prevent many of their children from becoming dependent because of the added years of parental care. Other factors are the extension of working men's compensation and insurance systems, which provide for support in case of sudden death of the father, the widow's pension funds operative in many states, and decreased immigration of foreigners with their large young families, where the death of the wage earner immediately throws several children into an institution. Thus it has come to pass that many of the orphan asylums do not receive enough applications to keep their capacity filled—in some cases they are only two thirds occupied—and of course all this is cause for congratulation, a happy corollary of the solution of some of man's social problems in economic and hygiene fields.

But another change has been noticed in orphan asylum population aside from the diminution in gross numbers. It is the type of child which is coming in constantly increasing proportions, namely, the abnormal, problem, or psychopathic child. A moment's reflection will reveal the reason. When one parent is removed by an untimely death, the surviving mother or father will often find it feasible, with the aid of modern social agencies, to retain the normal child, but feels that, without the help of the departed parent, he is unable adequately to handle the difficult pedagogical problems presented by the more difficult child, and consents to its transference to an institution. The number of full orphans of normal parentage has become comparatively small, but in their stead has come an increasing number of children, from disrupted homes or deserted by one or the other parent, or separated from parents considered by the courts to be unfit custodians of their own offspring. These children start life hampered by unfavorable psychic traits in so far as these may be considered directly transmissible and with the heritage of an environment fraught with neglect, unhappiness, and brutality in their earliest formative period.

While the orphan asylum, especially the modern cottage plan institution, does not seem to have entirely outlived its usefulness, even with our changing community life, there is an obvious tendency to admit to the institution a proper and increasing number of problem children, those suffering from stealing, lying, emotional outbursts, sexual deviations, rather than the more tractable "normal" boys and girls.

It is these particular deviations of conduct which present day psychiatry is attempting to unravel and correct and to study in the hope of the prevention of crime and delinquency in the generations to come. The immediate future may perhaps see some modern model orphan asylum converted into an experimental hospital school for the individual examination of this type of person who is often recognizable at a very early age. Certainly careful work undertaken at this youthful period, disheartening as it appears with the resources now at our command, would seem to offer more hope for alteration, cure and scientific enlightenment than similar efforts which have been undertaken in prisons and reformatories, when habit formation has become inured and set.

HETEROPHORIA

Heterophoria, or the tendency of one eye to deviate in one or another direction in consequence of imperfect balance of the ocular muscles, commonly known as loss of orientation, occurs after convalescence from the enucleation of an eye.

Mr. Percy Dunn, in the *Lancet*, July 10, 1926, deals with this condition from its several aspects, considering it chiefly from the economic point of view. As it is a question of as great interest in this country as in Great Britain, especially as regards its effect on the insurance companies, Mr. Dunn's opinions on the subject are well worth notice.

In the first place, it may be stated that the duration of the disability is generally a question of age. It usually varies between three and six weeks in young adults. In older men the period is longer. Further, no one eyed man should be permitted to resume his employment until accurate orientation has been established. If he does he runs risks of injury to himself and he is likely to be a source of danger to his fellow workmen.

From the economic point of view, the workman as long as the loss of orientation continues, in addition to the loss of an eye, is faced with this defective vision which largely reduces his earning capacity or may prevent him from following his trade. There-

fore, the insurance companies must compensate him until correct orientation has been restored, provided the disability has arisen as the result of accident in the course of employment. As a rule, the disability does not last long. However, the loss of orientation may become permanent and then the insurance company may have to pay a large sum for compensation in default of which the case may be brought into a court of law for settlement, and it is more than likely that the man will become a pensioner for life of the insurance company concerned. While this is a rare happening, it is one which may arise.

Lastly, Dunn considers the conditions under which heterophoria may assume a permanent form. It is pointed out that although binocular vision is present, heterophoria in one eye commonly exists as a latent form of disturbance of muscular equilibrium such as occurs in anisometropia, where the refraction in one eye is better than that in the other. In a general sense the better eye becomes the working eye, while the more defective one functions in a state of latent heterophoria, without, however, causing any disturbance to the vision. When, on the other hand, the working eye has been removed, with abolition of binocular vision, the latent heterophoria in the remaining eye becomes manifest, with the consequent loss of the power of accurate fixation, and the possible continuance of this as a permanent defect.

From the economic and compensatory viewpoint, some of the rules laid down with regard to the scale of compensation for loss or injury to vision by accident seem inconsistent. There appears to be room for reform of some of the existing rules for estimating the pecuniary value of certain forms of loss of vision due to accident.

There is one interesting point in the article in the *Lancet* referred to, and that is, that attention is rightly directed to the danger to himself and others of allowing a workman who has lost an eye and is suffering from a loss of orientation of doing any work which his defective vision may render dangerous.

ENGLISH SPEAKING CONFERENCE ON MATERNITY AND CHILD WELFARE

The fourth English Speaking Conference on Maternity and Child Welfare, in connection with the British National Association for the Prevention of Infant Mortality, was opened on July 1st in Caxton Hall, Westminster, more than seven hundred delegates being present. Sir Arthur Stanley presided at the opening session, his place being afterwards taken by Dr. Charles Hastings, medical officer of health of Toronto, Canada. Sir Kingsley Wood, president of the Congress and parliamentary secretary to the minister of health, in the absence of Mr. Neville Chamberlain, the minister of health, welcomed the delegates and said that the conference represented voluntary workers, members of the chief local authorities in the country, and supporters from overseas.

What the ministry wanted to see in connection with all health problems was a partnership between all voluntary organizations, local authorities, and government departments. The work of voluntary workers in connection with maternity and child welfare was one of the best features of the national life of Great Britain. The number of antenatal centres had increased during the past two years from 564 to 641, the number of maternity beds, in hospitals and homes, from 1,945 to 2,226, and no fewer than 1,347 were maintained by voluntary agencies. The number of infant welfare centres increased from 2,001 in March, 1924, to 2,218 at the present time. The 756 maternity and child welfare centres were run by voluntary agencies. There were 85 day nurseries run by voluntary effort and all but one of the 104 homes in which mothers and babies were kept together were maintained by voluntary funds. The infant death rate had fallen from 154 in 1,000 in 1900 to 75 in 1,000, a remarkable achievement. On the other hand, during the past twenty years there had been practically no diminution in the rate of maternal mortality, and the rate for deaths in the first month of life, and for stillbirths had been scarcely affected.

Obituary.

WILLIAM FRANCIS CAMPBELL, M.D.

Brooklyn

Dr. William Francis Campbell, one of the leading physicians and surgeons of Brooklyn, died in the Presbyterian Hospital, Manhattan, on September 8th, at the age of sixty-one. Dr. Campbell had won a high place in abdominal surgery, and it is a singular and unfortunate coincidence that he should have died after an operation for gallstone disease, an operation which he himself had many times performed and in which he was particularly successful.

Dr. Campbell was a native of Brooklyn. He was graduated from New York University in 1887, and took his medical degree from the Long Island Hospital Medical School, in which he later became professor of anatomy. At various times he acted as surgeon to the Seney Hospital, the Swedish, the Jewish, the Bushwick, and the Jamaica hospitals, and was for many years surgeon in chief of the Trinity Hospital. He had been president of the New York State Medical Society and the Kings County Medical Society and was a member of numerous organizations. He was the author of several books on surgical subjects, his *Surgical Anatomy* and *Surgical Diseases of Children* being especially well known.

BAD NEUENAHR

A Study Tour of Europe in 1926

RICHARD KOVACS, M.D.
New York

(*Cotninued from page* 371)

GERMANY

Hamburg, the big commercial port, situated along the Elbe River, and with beautiful residential sections around the two Alsterbasins, was the first German city visited. Among its excellent medical institutions we saw the unique Institute for Tropical Diseases, nicely built on a hillside overlooking the harbor. Many important researches in tropical pathology were effected in this institute, which also gives regular courses to ship surgeons and other physicians. In spite of the loss of all German colonies, this important work is going on just the same. Professor Nocht, the director, was absent in his official capacity as medical adviser of the League of Nations, and his associate, Professor Fulleborn, demonstrated the work. Next, the chief municipal hospital of Hamburg, the Eppendorfer Krankenhaus, was visited. It is a huge plant, with detached pavilions in splendid garden surroundings, housing about two thousand patients. The work of the surgeon, Kummel, and his successor, Siedeck, the internist, Lenhartz (deceased a few years ago), and others, made this institute known the world over. A large dental department, with special care to school children, is an important part of the hospital. Our party was entertained at luncheon on the beautiful grounds of the medical director, Professor Brauer, and many prominent Hamburg colleagues participated.

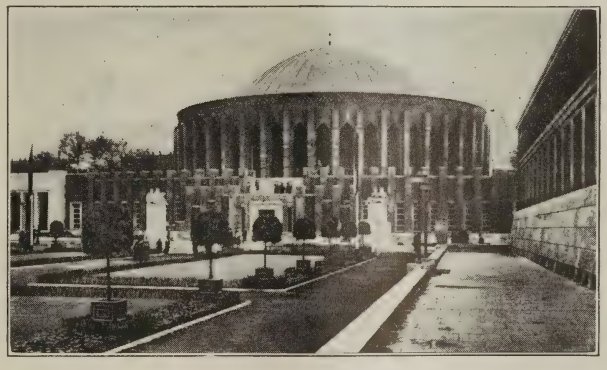
THE HEALTH EXHIBITION IN DÜSSELDORF

The hearty welcome in Hamburg found its continuation all along the Rhine cities and health resorts. A day was spent at Düsseldorf, one of the best laid out and most artistic centres of Germany, itself the seat of a medical academy for Postgraduate Study, in visiting the *Gesolei*, a monster health, social welfare and physical culture exhibition. As Professor Kraus, Rector of the Academy, emphasized, the exhibition along the banks of the Rhine, occupying 450,000 square yards on the right bank, was constructed with the heroic efforts over grounds two miles long that a few months before were serving as stables for the French troops and were deeply inundated a few weeks before the opening—in order to demonstrate that Germany has not lost its spirit for peaceful scientific research and progress. In speaking to German physicians, they all admitted that they, as the middle classes in general, have lost all of their savings and reserves, and are being reduced to one half to one third of their former incomes, but have resigned themselves to the situation, and see their

Roof Treatment on Lindenburg Hospital, Cologne
(New University Building)

hope, as well as that of their country, in uncomplaining, strenuous work.

Housed in imposing buildings, commensurate with Düsseldorf as an artistic centre, the great exhibition offers an amount of material which is simply overwhelming. Infant welfare work has its own building; "man in his relation to nature" shows the effects of climate and temperature; "history of mankind" portrays the development of the human race, beginning with prehistoric exhibits; "the transparent man," a most wonderful exhibit of the Dresden Museum of Hygiene, represents years of painstaking work, and makes every part of the full sized body, including bones and inner organs, visible and transparent like a microscopic slide. There is an exhibition of the history of medicine and natural sciences, a "doctor's house" with exhibits relating to the medical profession. In direct relation to disease there are sections on tuberculosis, on the care of nervous disorders, of the deaf, crippled and blind, on occupational diseases and industrial hygiene, on tropical medicine, on antialcohol work, on hospital and sick nursing (with the collaboration of the medical faculties of all universities) and of the international work of the League of Nations preventing epidemics. There are special sections on housing, on food and nutrition, on sport and physical exercises, on heredity and race hygiene, on social welfare and public assistance, and many others, all with characteristic neatness and thoroughness.



Planetarium, Düsseldorf

Of enormous general interest is the planetarium, a work of the great optical firm, Zeiss, which is a complete moving representation of the entire stellar system on the inside of a huge dome. As we sit underneath, the huge auditorium becomes by degrees completely dark, and a lecturing astronomist makes the planets, the stellar combinations, the moon, the milky way, and the complete firmament appear singly or in groups, and their exact movements can be reproduced at any desired speed. A miniature railway takes the visitors, without fatigue, from one end of the exposition to the other. Among the many visitors from near and far we noticed the numerous groups of school children taken there as part of their vacation. We feel safe in stating that the Düsseldorf exposition is the greatest health educational undertaking ever attempted.

COLOGNE

The historical city of Cologne (Köln), with its imposing dome overlooking the Rhine, is the seat of a university, the medical faculty having been created a few years ago out of the former Academy for Practical Medicine. We saw its clinical teaching department in the fine municipal hospital, Köln-Lindenburg, where we were greeted by Geh. Rat. Siegert, professor of pediatrics. We saw a most interesting and unique demonstration by Professor Schott of the carotissimus reflex in the dog and in man, a demonstration by Professor Zinsser of treating facial defects, especially those of the nose, by a prothesis made by the patient himself with a gelatine mixture out of a model furnished to him. Professor Dietrich showed very fine pathological specimens, and Professor Tilmann demonstrated interesting surgical work for epilepsy. A splendid luncheon in the physicians' casino ended our visit.

BAD NEUENAHR AND WIESBADEN

Two hours from Cologne, in the valley of the Ahr, a rapid running tributary of the Rhine, lies the picturesque and attractive spa Bad Neuenahr, at the foot of an impressive basalt mountain. It is a comparatively new resort, its warm springs having been discovered only seventy years ago by a wine grower whose grapes would not ripen on a certain part of his property where the ground was always wet. Today these springs occupy the unique position of being the only alkaline thermæ of Germany, issuing

Group of Physicians in Front of Hospital de la Pitie, Paris

Group of American Physicians in front of *Kurhaus,* Wiesbaden

at a degree of 96° F. The well known Apollinaris spring is also located in Neuenahr. Kurdirektor Rüttner showed us around the beautiful modern baths, which include complete hydrotherapeutic outfits, thermal, Russian, sand, mud, light and other baths, radium emanation and inhalation rooms. The mineral springs indicated in a score of important medical conditions, arise in great open basins, the *Sprudels.* At the time of the American occupation, a lady rushed indignantly one morning into the office of the *Kurdirektor,* as she had found a nude man in the basin, when she went for her morning drink. He proved to be one of the doughboys who mistook the *Sprudel* for a tub. The wonderful dinner and entertainment in our honor on the eve of July 4th proved, however, that there were no hard feelings left. The surroundings of Neuenahr, vineclad, ragged hills topped by castles and ruins, at their base swift running mountain streams, furnish as romantic sights as ever delighted the hearts of tourists.

Taking the most wonderful part of the Rhine trip from Coblenz to Bieberich, the landing station for Wiesbaden, we arrived at this oldest and largest of the German spas, situated in a closely wooded valley of the Tannus mountains. Even Pliny mentions the warm springs of *Mahincum* where the fourteenth legion erected a castle. Nowadays not less than twenty-seven active springs yield approximately two million quarts of water daily, which is used for bathing, drinking and inhalation. The drink cure is carried out daily on the fine promenade of the Kochbrunnen, and is set to music. A magnificent municipal establishment and sanatorium, the Kaiser Friedrich Bad, completed just before the war, contains a most complete equipment of every hydrotherapeutic and physiotherapeutic measure known. Before the war the average yearly number of visitors was 200,000, which is now reduced about one half. We noticed the continued Allied military occupation, Wiesbaden being the headquarters of the Second British Rhine Brigade. A British officer, when spoken to about our surprise at still finding a military occupation, gave the characteristic reply, "So are we." The occupation, however, seems to be going on very amicably, especially as Wiesbaden offers such an ideal combination of a spa with metropolitan attractions. The day of our arrival being July 4th, we were guests of honor on the terrace of the wonderful Kurhaus, and witnessed some elaborately artistic fireworks, and next day the municipality tendered a splendid banquet to us. The Wiesbaden Medical Society took an active part in all arrangements for the study of the various institutions, and we heard the announcement that funds were appropriated to establish and maintain a great institute of balneology and metabolism in Wiesbaden. As the first one of its kind in Germany, one of its objects will be to put the extensive empirical knowledge of the therapeutic action of mineral waters and hydrotherapeutics on an exact scientific basis. A very delightful excursion to the champagne factory at Eltville, a suburb of Wiesbaden, was made on the second day of our visit.

HEIDELBERG

The world famous university city was visited next and two days spent there. The ruins of the castle in beautiful position overlooking the Neckar River are impressive in the daytime, and leave a never to be for-

gotten reminiscence of romance when illuminated at night, as we saw them. The *carcer*—student prison—and the students duelling are other unique sights, although the latter pastime has just been made an offense punishable with five years of imprisonment by the new German democracy. The medical faculty of

Hôtel Dieu, Paris. Central figures, Prof. Gilbert, Internist, and Prof. Hartmann, Surgeon

the university, under the leadership of Professor Morro as Dekan, met us at a banquet full of friendly sentiment. The next day was spent in listening to the regular lectures in the historic lecture rooms in which so many men of international fame have taught. Our greeting by the student body was also quite hearty, consisting, according to best German custom, of continued loud stamping. Professor Krehl gave a medical, Professor Morro a pediatric, and Professor Enderlen a surgical clinic, and Professor Menges one in gynecology. Heidelberg offers splendid post-graduate facilities to American physicians, and, according to the decision of the faculty, there are no charges whatsoever for those who join any clinic for any length of time. Unfortunately, there is not enough English spoken there.

BADEN-BADEN

Baden-Baden, the last German health resort visited, lies in the valley of the little river Oos, in the northern part of the Black Forest. Its history dates back 1800 years, as the *Roman ruins*, which we saw subterraneously, are the remnants of extensive hot baths built by Emperor Hadrian. Around the river there is a very extensive *Kurpark*, magnificent gardens with many subtropical trees and shrubs, surrounded by pineclad mountains, some of them 3,000 feet high. The springs are radioactive saline thermal springs, and their curative value in a great number of chronic inflammatory conditions is world renowned. The great cure establishments, the Friedrichs and Augusta Bad and the Inhalatorium are directly under the control of the State of Baden and contain a therapeutic equipment of first order. The Kurhaus is a magnificent building in which international history has been made, and the banquet given in our honor there surpassed in splendor and cordiality everything enjoyed before. The next day we were taken for an automobile trip through adjoining parts of the Black Forest.

SWITZERLAND

Eight days were spent in Switzerland, "the tourist's paradise," and a partial holiday of clinics observed. We saw attractive Zurich with its large lake surrounded by mountain ranges and its fine shops; beautiful Luzerne on the Viervaldstatter See, with the Rigi, Stanserhorn and Pilatus towering right above, and the celebrated "dying lion" chiseled in the face of a rocky cliff; Interlaken with its cosmopolitan life; and ascended the *Shynige Platte*, enjoying a unique sight of the Mönch, Jungfrau and Eiger; and, as a final climax, making an excursion from Geneva into the French territory of Chamonix, ascended the wonderful *mer de Glace*—one of the glaciers of the Mount Blanc range.

In Berne, the capital of Switzerland, two days were spent attending the University clinics. Our host, Professor de Quervain, a worthy successor of Kocher, showed thyroid and traumatic surgery, and

Court of Army Museum, Val de Grace, Paris. Professor Dopter, Curator and Dr. Fred H. Albee

also demonstrated his good results with resection of gastric ulcer. The well known internist, Professor Sahli, gave a clinic on dysbasia angiosclerotica. He contends that our methods of measuring blood pressure give unreliable results on both systole and diastole. He measures the systolic pressure alone with a delicate spring and water balanced graphic manometer. A model physical therapeutic institute is attached to his clinic. The language of teaching in Berne, as well as in Zurich, is German, while in Lausanne and Geneva it is French. We saw the unique cretin farm, an institution for the care of the numerous cases of congenital or acquired cases of cretinism due to hypothyroidism.

(To be concluded)

News Items.

New School for Blind.—A special free school, conducted on Pelham Parkway by the New York Institute for the Education of the Blind, has been opened to pupils from the neighboring counties of both New York and New Jersey. An attendance of more than one hundred is anticipated.

Illinois Mental Hygiene Committee.—Announcement has been made of the organization of the Central Illinois Committee for Mental Hygiene, with the following officers: Honorary chairman, Dr. Frank P. Norbury; chairman, Dr. A. L. Bowen; secretary-treasurer, Mrs. S. J. Hanes. In addition to these officers, nine vice-presidents representing various districts have been appointed, and twenty-five directors elected.

Coming Meetings.—Future conferences and conventions of interest include the following: National Tuberculosis Association, October 4th-7th, Washington, D. C.; American Public Health Association, October 11th-14th, Buffalo; Health Officers and Public Health Nurses, October 12th, Buffalo; Association of Military Surgeons of the United States, October 14th-16th, Philadelphia; National Recreation Congress, October 18th-22d, Atlantic City; Pan Pacific Conference on Education, Rehabilitation, Reclamation and Recreation, April 11th-16th, 1927, at Honolulu, Hawaii.

New Bellevue Psychopathic Pavilion.—Announcement has been made by Joseph V. McKee, president of the Board of Aldermen of New York City, that it has been recommended to the Board of Estimate that the city acquire as the site for the proposed new Psychopathic Pavilion of Bellevue Hospital the block bounded by Twenty-ninth and Thirtieth Streets. First Avenue and the East River. The new pavilion will cost approximately $3,000,000, and, that the project may not be delayed, $30,000 of this amount has been made available to permit the employment of an architect to prepare plans and specifications.

Lectures at the New School for Social Research.—Among lectures of interest announced by the New School for Social Research, New York City, are the following: Selected Chapters in the Theory and Practice of Psychoanalysis, by Dr. S. Ferenczi of Vienna; Conduct and Its Disorders in Childhood and Adolescence, by Dr. Ira S. Wile; Fundamental Problems in Adult Education, by Everett Dean Martin; Educational Psychology, by Leta S. Hollingworth, Ph.D.; and Mental Hygiene: Its Personal and Social Aspects, by Dr. Frankwood E. Williams. The fall term of the school began on October 4th.

New York Health Demonstrations.—Arrangements have been made so that those attending the annual meeting of the American Public Health Association in Buffalo, October 11th-14th, may take advantage of the opportunity to visit two of the New York State Health Demonstrations which for the past few years have been receiving financial assistance from the Milbank Memorial Fund. Two of these demonstrations are situated respectively in Syracuse and in Cattaraugus County, both conveniently situated respectively in Syracuse and in Cattaraugus County, both conveniently situated for a visit from Buffalo, and the third is in New York City.

Research on Surgical Supplies.—According to Dr. E. R. Weidlein, director of the Mellon Institute of Industrial Research, University of Pittsburgh, the firm of Johnson & Johnson, manufacturer of surgical supplies, New Brunswick, N. J., has established at the institute a fellowship that will study the exact requirements of surgeons and other medical specialists in the way of sundries, with the joint aim of developing new supplies that are needed and of standardizing the products now in use. An investigation will also be made of the processes of renovating used supplies, and several other Industrial Fellowships of the Institute will coöperate in devising satisfactory procedure.

Dr. Frederic H. Slayton will be in direct charge of this comprehensive research. The fellowship will be operated in a totally unbiased and independent manner, in accordance with the Mellon Institute system, and all its investigations will be conducted primarily for the benefit of the public. It is the plan to report the results in appropriate periodicals as the various phases of the studies are concluded.

In carrying on this work, Dr. Slayton and the Institute's executive staff invite the concurrence of all interested organizations. They are especially desirous of securing the close collaboration of hospital executives and of members of the medical profession.

American College of Physical Therapy.—The American College of Physical Therapy will meet at the Drake Hotel, Chicago, October 18th to 22d. As arrangements now stand, the first two days will be devoted to instruction classes. Plans are on foot to enlist the services of some eminent Europeans to participate in the program.

Travel Study Club Elects Officers.—At the completion of its recent European study tour, the Travel Study Club of American Physicians elected the following officers: President, Dr. Fred H. Albee, of New York City; vice-presidents, Dr. Edward B. Heckel of Pittsburgh, and Dr. John P. Lord, of Omaha; secretary, Dr. Richard Kovacs of New York. Plans are being made for the next study trip, covering Central Europe, including Germany, Austria, Czechoslovakia, Hungary and Italy.

Columbia to Extend Public Health Work.—Announcement has been made that Columbia University's public health work, carried on through the DeLamar Institute of Public Health, will be extended this year. The object will be to supply to the lay public through channels of popular education the benefits of reliable information in the protection and development of human health and in the prevention of disease. Dr. Haven Emerson is director of the DeLamar Institute, which is a part of the School of Medicine. Beginning with the coming academic year, the institute will award the degrees of Master of Science and of Doctor of Philosophy.

First Polish Nursing School Established.—The profession of trained nursing was definitely established in Polish hospitals early in July, according to a dispatch to the *New York Times,* when Miss Amelia Greenwald of Alabama officially turned over to Polish control the most important nursing school ever attempted in Warsaw. The institution, which physicians declare will revolutionize medical conditions throughout the country, is the gift of the Jewish people of America through the late Joint Distribution Committee. Its success through the sole efforts of Miss Greenwald, after three years of struggling against nearly insurmountable obstacles, is one of the most interesting results of post war relief work abroad as well as one of the highest importance. Miss Greenwald worked during the World War at several base and evacuation hospitals, and at the embarkation camp at Brest had charge of the French war brides.

Personal.—Prof. Friedrich von Müller delivered the Edward G. Janeway Lectures at the Mount Sinai Hospital of New York on October 1st and 2d. He spoke on the nervous system and internal medicine.

Dr. Herman Goodman, of New York City, recently addressed the twentieth annual convention of the Illuminating Engineering Society, and also the convention of the American Electrotherapeutic Association. The first lecture was on Light in Medicine and Surgery, and the second on Physics and Biology of Light Dermatology.

Dr. Philip R. Lehrman, chief of the psychiatric clinic at the New York Postgraduate Medical School, and consulting psychiatrist at the Manhattan State Hospital for the Insane on Ward's Island, returned recently from a European tour of psychiatric centres.

Dr. C. A. Mills, who perfected the method used in isolating and purifying tissue fibrinogen, has been sent by the Rockefeller Foundation to Peking University for two years as instructor in medicine and for experimental and research work. Dr. Mills has been granted leave of absence from his position as professor of internal medicine at the Medical College of the University of Cincinnati.

Dr. S. S. Goldwater, director of Mount Sinai Hospital, New York City, has recently returned from a tour of European hospitals.

Dr. Pedro N. Ortiz, Commissioner of Health of Porto Rico, was a visitor in New York City during the summer. Dr. Ortiz visited also in Boston, Philadelphia and Washington.

Dr. Edouard A. Rist, of Paris, has been in this country as one of the delegates to the International Tuberculosis Conference recently held in Washington. Dr. Rist among other addresses made one before the annual clinical congress at Yale University, after which he was tendered a reception and banquet at the New Haven Lawn Club.

Dr. Tom A. Williams, who left Washington last winter to practise his specialties, neurology and psychiatry, in Florida, is recovering from a fracture of the humerus and has now resumed work at his office in the Exchange Building, Miami, Florida.

Book Reviews

ENDOCARDITIS

Studies on Bacterial (Infective) Endocarditis. By William S. Thayer. The Johns Hopkins Hospital Reports. Volume XXII, Fasciculus I. Baltimore, 1926.

This monograph by Dr. Thayer is based on careful clinical, anatomical and bacteriological studies of 198 cases of bacterial endocarditis, of which 138 came to necropsy. For the sake of comparison, twenty-four instances of uncomplicated fatal acute rheumatic heart disease were analyzed as well. Some of the results of this study are worthy of repetition. Terminal streptococcal infections in rheumatic heart disease are common. Over a quarter of the instances of acute myocarditis found in fatal streptococcal infections showed anatomically the characteristic lesions of rheumatic heart disease. There was only one case of bacterial endocarditis caused by other organisms in which rheumatic lesions were found as well. This suggests a close relationship between streptococcal infections and "rheumatism." Of the cases of bacterial endocarditis, fifty-five per cent. were due to the streptococcus, thirteen per cent. to the pneumococcus, twelve per cent. to the staphylococcus aureus, eleven per cent. to the gonococcus, four per cent. to B. influenzæ. The incidence of gonococcal infections is unusually high. Most of the cases of fatal rheumatic heart disease prevailed in the first two decades of life, the gonococcal infections occurred especially between the ages of twenty and thirty, streptococcal endocarditis prevailed in middle adult life, pneumococcal endocarditis in middle and later adult life, and staphylococcus aureus at all ages. In a short review it is impossible to bring out the many interesting facts resulting from Dr. Thayer's investigations which have extended over many years. The book well merits careful perusal. Most clinical statistical studies are rather unsatisfactory. Dr. Thayer's material is unusually complete and well arranged, and this, coupled with the critical analysis by a ripe and exceptionally able clinician, makes this monograph a model of its kind.

BLOOD SUGAR REGULATION

Studien Ueber die Blutzuckerregulation bei Epinephrektomierten Tieren. C. G. Sundberg (Doctorate thesis, University of Upsala) (also published in Svenska Lararesallskapets Handl., 1925, *51*, 61.)

In a ninety-eight page monograph, the author narrates his experiments on the blood sugar level of normal and suprarenalectomized rabbits together with their alimentary tolerance for glucose, levulose and galactose, using from two to five gms. sugar per kilo of body weight given orally as a twenty per cent. aqueous solution. He found that in normal rabbits the rise in the blood sugar began, on the average, about forty minutes after administration, whereas in suprarenalectomized rabbits this was delayed, in one case, as long as three hours. He noted, as has been observed by many others, that the blood sugar in suprarenalectomized rabbits progressively decreases to death after the postoperative hyperglycemia. Epinephrine causes hyperglycemia in suprarenalectomized as well as in normal rabbits. Suprarenalectomized rabbits are much more sensitive to insulin than normals—hypoglycemic symptoms being produced in a much shorter time and with less than one half the dose required for normals. He found no difference in the effect on the blood sugar of normal and suprarenalectomized rabbits following thyroxin injections. He made forty-seven transplants in a total of thirty-two rabbits and obtained necrosis of the transplants in sixty per cent., while in forty per cent. definite regenerating cortical transplants were recovered. Several excellent photomicrographs illustrate this regeneration. In comparing the duration of life of doubly suprarenalectomized rabbits with and without transplants, he shows that the lives of those rabbits having active transplants were prolonged. He found accessory suprarenals in but seven of forty-two rabbits examined.

PHYSIOLOGY OF NUTRITION

Troubles des Echanges Nutritifs. Par Professeur Ch. Achard. Paris: Masson et Cie, 1926.

In this excellent book Achard first describes the physiology of nutrition (exchange of all material required). Based upon the latter the disorders arising from the elementary disturbances of these ingredients are analyzed and the clinical morbid phenomena explained. The total amount of iron, which plays such an important part in the life of every living organism, amounts in a full grown human being to three or three and a half grams. The body receives the iron principally in organic combination, contained in the different foods. Foods rich in iron are the following: red meats, the yolk of eggs, green vegetables (spinach, cabbage, asparagus), and red fruits. The total daily quantity of iron eliminated by the body amounts to thirty milligrams, of which one to eight milligrams appear in the urine. The hemoglobin of the blood contains most of the iron and by its quality of binding oxygen loosely makes life possible. When blood is destroyed by the processes of life, the hemoglobin is changed into bilirubin, an isomer of hematoporphyrin, a substance not containing iron. The bilirubin is then excreted by the liver in the bile, while the iron is temporarily stored in the liver.

Achard's work is extremely useful and highly commendable.

LOCAL ANESTHESIA IN NOSE AND THROAT SURGERY

Local Anesthesia in Otolaryngology and Rhinology. By James Joseph King, A.M., M.D. With a supplement on the Toxic Effects of Local Anesthetics, by Emil Mayer, M.D. Preface by Robert Hatcher, M.D. Twenty-one Illustrations and a Folded Table of Cases. New York: Paul B. Hoeber, Inc., 1926.

As local anesthesia is gradually but surely gaining ground in every branch of surgical endeavor, its advantages as well as its limitations are becoming clearly and positively established, so that in the near future we shall be in possession of an agency of a definite nature to be applied with safety and due caution.

Dr. King's work is a decided step forward in this direction, and he has performed a distinct service to otolaryngology by collating and presenting in a readable and well digested form everything of importance

concerning local anesthesia in the surgery of the ear, nose and throat. The value of the work is greatly enhanced by the author's personal surgical experience both in private and hospital cases. He aims—and does it successfully—to bring order out of the chaos in the minds of many of the operators both as to the nature and methods of employment of the various local anesthetics that have been responsible for avoidable mortality, by elaborating on his own technic and that of other responsible operators whereby anesthesia can be accomplished safely and quickly. The description of the author's methods is gone into most thoroughly and minutely, so that a careful reader can acquire the technic without great difficulty.

The second half of the volume is taken up with reports of the Special Committees of the American Medical Association on the toxicity of local anesthetics in nose and throat work, that should be carefully perused by every practising laryngologist.

The book contains an interesting table of cases. It is heartily recommended as a useful guide for every nose and throat man.

THE NASAL SINUSES

Pathology and Treatment of the Inflammatory Diseases of the Nasal Accessory Sinuses. By Professor Dr. M. Hajek, Chief of the Laryngorhinootological Clinic, University of Vienna. Translated and edited by Joseph D. Heitger, A.B., M.D., and French K. Hansel, M.D., M.S. Fifth Edition, completely revised and enlarged. In Two Volumes. St. Louis: The C. V. Mosby Company, 1926.

Dr. Hajek's work in the original German has been considered a classic these last twenty-five years, written as it was by one who is a pioneer in the field of sinus disease, and who still remains as one of our greatest authorities on everything pertaining to the science of sinuses. The English edition is a distinct gain to our as yet comparatively meagre literature on the subject, the more so as it covers the entire field in a thoroughgoing, systematic and comprehensive manner. In this work is incorporated the experience of a prominent teacher and practitioner extending over a period of more than forty years, as a result of which, as the translators truly observe in their preface, the subject of sinus disease is "for the first time placed on a solid foundation."

The treatment of the individual sinuses is preceded by the general part which embraces within its 150 pages considerations as to the normal anatomy, pathogenesis, symptomatology and diagnosis of paranasal sinuses in general. Then every individual sinus is gone into with characteristic attention to details and a scrupulous avoidance of nonessentials that tend to enhance the value of the book as a guide to the practising physician. A decidedly refreshing feature, at the present time, when a veritable *furor operativus* in things rhinological is raging, especially among the younger laryngologists, is the author's leaning toward conservative treatment of sinus conditions before the final, inevitable resort to operative intervention. It would be a work of supererogation to pick out any part of the book for special praise, but the reviewer was particularly impressed by the extensive chapter on inflammations of the maxillary sinus that contains within its pages all of our present knowledge on the pathology and treatment of this most important subject.

A comprehensive bibliography adds materially to the value of the work.

DISEASES OF THE EAR

Politzer's Textbook of Diseases of the Ear. Sixth Edition, revised and largely rewritten. By Milton Ballin, M.D., Ph.B. With 302 Illustrations. Philadelphia: Lea and Febiger, 1926. Pp. xiii-776.

The reappearance, after a protracted interval, of a new English edition of Politzer's work on diseases of the ear is a welcome addition to our ever growing otological literature in which it will justly occupy a position second to none. The editor, fully aware of all the advances made in this field during the period intervening between this and the preceding edition, has revised and largely rewritten the entire work, has added to the body of the book, and has eliminated what appeared to him as nonessential or antiquated, without impairing the intrinsic value of the original work, thus bringing it fully up to date, that it may truly fulfill its mission of a textbook for practitioners and students.

We were particularly impressed by the thoroughness of the anatomical and pathological data, while the treatment is everywhere characterized by a refreshing conservatism which is the more valuable as it comes from one who stands on a firm ground and has perfect control over his subject. The chapters on the methods of physical examination of the organ of hearing and middle ear disease deserve special mention for their thorough, lucid and painfully detailed description, where nothing is taken for granted, and every important point is clearly and forcibly emphasized.

More copious as well as more recent references to American authors would greatly enhance the value of this work.

MEDICAL RELIEF IN RUSSIA

Report of the Medical Director of the American Medical and Sanitary Relief in the Russian Famine, 1921-1923. By Col. Henry Beeuwkes, M.D., assisted by Maj. W. P. Davenport, M.D. Special Edition.

This special edition of the directing physicians' report of American medical and sanitary relief in the Russian famine during 1921-1923, in variance with those distributed generally, contains photographs of disease and famine manifestations furnished only to the medical profession and press.

The report states that the epidemics following in the wake of Russia's disorganization and famine in 1921 threatened not only the whole population of civilized European Russia, but those of Eastern and Central Europe as well. The results of the large scale medical relief in combat of epidemic causes shows what can be done by organized effort even when mobilized and put into action on short notice. Uncovering the facts of decline of public health, of agriculture, industry and welfare, the report carries much valuable source information on conditions in Russia after war, revolution, and the four years of social experimentation, on a great mass of population.

Cholera among the Russian people had increased over twenty fold from 1919 to 1921; typhus, only a nominal menace in 1919, had leaped from 130,000 cases to nearly three million in 1920, and again in 1921 threatened to increase far beyond control; relapsing fever, normally not exceeding 30,000 cases annually, reached over two million. Step by step with these typhus fever rapidly doubled, then trebled, and more, as also did malaria, tuberculosis, hunger edema,

and other deficiency diseases. All the while starvation, hunger, weakness and exposure, insanitation, shortage of even the most elementary medicines, made for ideal propagation of almost every known disease.

Upon the initiative of Herbert Hoover, backed by general appropriations by Congress and the American Red Cross, the comparatively small unit of American physicians by departing at once for Russia were able to supply overworked Russian physicians and overcrowded hospitals with pitiably needed medicines and supplies. Through the organization of a wide combat of epidemics, and hand and hand with America's sixty million dollars famine relief fund, this medical unit had not only to supply eight million dollars' worth of medical relief, but also to get supplies transported over broken down railways to broken down institutions, assuring aid at strategic points. The work was in charge of Colonel Beeuwkes, assisted by Major Davenport and about sixty other American physicians from all parts of the United States.

In a preliminary section, the report outlines the development of medical practice in Russia from the time of Boris Godunov, through the reigns of Peter the Great and Catherine—the former was a physician of sorts—into the Zemstvo organization of rural medicine, down to the organization of the present Soviet Commissariat of Health. Other chapters treat of sanitation in Russia, hospitals, homes, and other institutions as the Americans found them; of food conditions, cannibalism, starvation, and their treatment. There is a detailed section on the epidemics which is a distinct contribution to medical knowledge of value both to the administrator and to the specialist.

The second part of the report records the actual carrying out of the American operations, and the peculiar problems met during the unprecedented campaigns, and should be of particular value to the organizer and student of social conditions as well as to the medical profession.

HYDROPHOBIA

Lyssa Bei Mensch Und Tier. Von Prof. Dr. R. Kraus, Dr. med. vet. F. Gerlach, und Dr. F. Schweinburg. Mit 69 Abbildungen im Text und 6 farbogen Tafeln. Berlin, Wien: Urban & Schwarzenberg, 1926. Pp. viii-464.

In spite of the marked progress that has been made in the methods of treating and preventing hydrophobia, this dread disease is still quite prevalent in civilized countries. Indeed, such a simple measure as the muzzling of all dogs has proved to be effective. Physicians, clinicians, veterinarians and hygienists ought to be familiar with this disease, especially in the diagnosis, the indications for prophylactic inoculation, the prophylactic sanitary measures. No complete work on this subject has been published during the last fifteen years. The authors have, therefore, assumed the task of supplying such a work and have practically produced a cyclopedia on the subject. They have not only reviewed all the available literature on hydrophobia, but have also published their own extensive experience of years. They state their own views on such practical questions as the etiology, postvaccination paralyses, prophylactic inoculation of man and dogs, etc.

Up to the present time, hydrophobia is the only incurable infectious disease. It is emphasized that it is the duty of legislatures to endeavor to provide conditions that will cause this disease to disappear wherever it is still prevalent, as it has actually been done in countries like Australia, Sweden, Denmark and Holland, where the disease is no longer seen.

The bibliography is most complete and includes the literature of the world. The book deserves the highest praise in every respect. It gives a complete discussion of every aspect of rabies in man and animals.

Medicoliterary Notes.

According to a booklet recently issued by the Field Museum of Natural History, of which Dr. James B. McNair is the author, ferric chloride is both a preventive and cure for most cases of ivy poisoning. Dr. McNair advocates a mixture consisting of one part by weight of ferric chloride with ten of alcohol and ten of water, to be applied to the skin and allowed to dry there before entering places where poison ivy grows, and also after possible exposure.

Opportunity, the Journal of Negro Life, published by the National Urban League, contains in its August issue two articles of interest to the medical profession. These are one instalment of the series of articles by Annaj Thompson on a Survey of Crime Among Negroes in Philadelphia, and Immunity to Disease Among Dark Skinned People, by Dr. Charles H. Garvin, of Cleveland, Ohio. Dr. Garvin is a member of the staff of Lakeside Hospital.

* * *

The Children's Bureau has recently issued as Bureau Publication No. 153 a pamphlet entitled *Standards of Prenatal Care; an Outline for the Use of Physicians.* No attempt is made in this publication to direct actual treatment, the physician using the outline being referred to standard works on obstetrics and other branches dealing adequately with the work. Two other useful contributions to obstetrics are reprints from the *American Journal of Obstetrics and Gynecology* of papers read at the thirty-eighth annual meeting of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons at Hot Springs in September, 1925. These are The Incompatibility of Pregnancy and Fibroids of the Uterus, by Dr. George Clark Mosher, and the Report of the Joint Committee on Maternal Welfare.

* * *

A person signing himself—or herself—A Returning American, writes in the *Atlantic* for August an article entitled Home, in which an account is given of the writer's impressions of New York upon returning from a visit to England. This is a very timely and significant contribution to our present methods of life in the Great City. The first thing that was found to contrast with English cities, including London, was New York's unbearable noise, most of which is unnecessary since London does not have it. Another thing was the "utter breakdown of law and of protection to the citizen by his government in America." He tells us that in London it is not necessary to use armored cars for transporting money, and describes the transfer of five millions in gold arriving from South Africa to the Bank of England. "At the dock," he writes, "it was placed in an open dray, a tarpaulin was drawn over it, and it was driven to the bank with no guards of any sort." After commenting upon the terrible pace at which we are living and also spending our money, he writes in conclusion: "How long can American nerves and minds and the American soul withstand the pressure and pace of America's present insane and noisy life, and the increasing restrictions on independent thinking and individual expression? There are ample signs that a devastating financial and commercial panic is not many years distant. Will the newer rich who may arise after it lead us a livelier dance yet, or will the history of the orgies of extravagance following the Revolution and the Civil War be repeated and a period of returning sanity ensue after the financial bloodletting?"

* * *

The *Monthly Labor Review* for August contains among other articles of interest a description of welfare work in the British coal industry, and a rather full summary of the Industrial Accident Conference held at Washington, D. C., July 14th-16th.

* * *

The Section on Hygiene of the League of Nations has recently issued as Publication III a *Rapport sur le Voyage d'etudes de la Commission du Paludisme en Espagne.* This is one of the documents of which no English translation will be published.

* * *

The *Franco-Russian Review of Medicine and Biology,* in commenting on the recent Pan-Ukrainian Hygiene Conference, gives a summary of a survey made among the peasants of the country. Through this it came to light that twenty-five per cent. of these never used soap; sixty-five per cent. used less than two pounds of soap per capita annually; and only eleven per cent. used more than three fourths of a pound a year; only two per cent. had washstands, and ninety-six per cent. possessed one towel; seventeen per cent. bathed only once a week, eighteen per cent. once a month, and sixty-three per cent. hardly at all. These conditions were not due to poverty alone, for it was found that the wealthy peasants often did not use more than a pound of soap a year.

* * *

The Mexico Department of Health has issued orders banning the dancing of the Charleston in public dance halls, on the ground that it is so violent that it is likely to cause heart failure. The order adds that the dance is "ugly and ungraceful; that it consists of contortions and the loosening of joints which are prejudicial to health, and that it is antagonistic to all artistic appearances." The department appeals to cafés and private ball rooms to abandon the Charleston for the above reasons.

Austrians are the greatest meat eaters in the world, according to a recent report. Italians eat the least. The annual per capita consumption in Austria is 245 pounds; in Italy, 23 pounds. Americans consume 118 pounds, the English 110, Norway and Sweden 86, the French 73, the Germans 70, and the Spaniards 49.

The Division of Venereal Disease of the U. S. Public Health Service has recently issued a Venereal Disease Manual for Social and Corrective Agencies, the purpose of which is to further acquaint individuals and organizations interested in education and social welfare with the role played by venereal diseases in the development of serious pathologic conditions which adversely affect the social structure. The book is designed for court and probation officers, social workers, nurses, visiting teachers, jailers and wardens, policemen and policewomen, and superintendents and matrons of homes for the dependent, delinquent and defective classes.

A new method for the treatment of diabetes through the injection under the skin of small quantities of nickel and cobalt has just been made known to the Academy of Science of Paris by Professors Gabriel Bertrand and Mac-Heboeuf, two French doctors. So successful has been the application of this treatment that all trace of sugar disappeared in many instances. However, a series of careful observations made by Prof. Francis Hathaway and Mlle. Levine confirm the general effectiveness of the new treatment.—*N. Y. Times.*

Abstracts from Current Literature

GYNECOLOGY AND OBSTETRICS

Treatment of Uterine Infections by Drainage.—Remington Hobbs (*Clinical Journal,* July 28, 1926) maintains that in septic cases with retained products the patients do far better if drained and no attempt made at operative intervention. The fact that intermittent temperatures occurring in cases of chronic inflammation of the uterus are controlled by drugs which relieve congestion, proves clinically that the primary cause is one of chronic inflammation of the endometrium. Therefore, it is not necessary to use the curette except for diagnostic purposes, viz., carcinoma or submucous polypi; still less is it necessary to perform hysterectomy. The use of strong antiseptics is likely to be followed by an increase in temperature, pain, discharge, and hemorrhage. Drugs such as glycerine and salt solution encourage the antimicrobic flow of blood through the infected tissues and affect the course of the disease. The persistence of red lochia is one of the most important signs of sepsis following labor or miscarriage. The uterus cannot be cleaned in one attempt. The problem of saving the most serious cases, those with blood infection, remains yet to be solved; to this end continuous research is necessary with skilled laboratory workers acting in close collaboration with those who understand the technic of draining the infected tissues.

Vaccinotherapy of Gonorrhea in the Female.—Inasmuch as Friedr. Wolff (*Zentralblatt für Gynäkologie,* April 17, 1926) was not satisfied with the results he obtained with stock vaccines. He therefore used his own vaccines which he prepared from a clinically virulent case of acute gonorrhea or an acute complication of an old gonorrhea (even from infections in the male), to which was added a 0.5 per cent. carbolic acid solution. Old vaccines, both autogenous and stock, become decomposed and form endotoxins, which frequently produce unpleasant byeffects. The dose given was five hundred million bacteria, which was gradually increased at intervals of three days. The author injects the living cultures subcutaneously. The immune bodies are apparently developed in the tissues, sometimes to a greater degree from stock than from autogenous vaccines. Phlegmons may develop as a result of the injection, but these readily respond to treatment and leave indurations behind. Usually one inoculation is sufficient.

The clinical results with this treatment are satisfactory, especially in protracted cases of gonorrhea, which show no tendency toward healing after two to three months. Cases of urethral infection do not respond as well as the uterine infections, and consequently local treatment is also necessary. Although as a rule local treatment, under certain circumstances in association with inoculation with killed fresh vaccine, is sufficient, the obstinate cases should be treated with living vaccine, which frequently produces surprising results.

A Probable Sign of Pregnancy.—C. J. Gauss (*Zentralblatt für Gynäkologie,* April 3, 1926) has noticed that during the early months of pregnancy the cervix uteri shows an abnormal mobility against the body of the uterus, so that the cervix can be moved laterally, anteriorly and posteriorly against the body of the uterus, without the latter taking part in the movement. This phenomenon is practically never found in the nonpregnant uterus, in which case when the cervix is moved to the left, right or posteriorly, the body always moves in the opposite direction.

The technic of the test is as follows: With bimanual palpation, the external hand pushes the uterus, which is in typical, slight anteversion flexion, against the vertebral column, while the extended index and third fingers of the other hand in the vagina grasp the cervix and push it alternately sagitally and transversely. The external hand can then feel whether the fundus of the uterus follows the movements of the other hand or not. In doing this test, one must be careful not to be confused by looseness of the mucosa on the cervix. This mobility is not confined to the mucosa of the cervix, but also affects the entire cervix up to the isthmial portion, between the anatomical internal orifice of the cervix and the histological internal orifice. This is called isthmial mobility of the uterus. There will be no confusion if the two fingers of the internal hand are carried well up into the fornix of the vagina. This sign is a modification of Hegar's sign and the author found it present in 146 out of 148 pregnancies within the first two months of pregnancy. It is comparatively rare in the nonpregnant uterus.

Etiology of Accidental Hemorrhage and Placental Infarction.—Francis J. Browne (*British Medical Journal,* April 17, 1926) has found that by setting up a chronic oxalate nephritis and then causing an acute exacerbation of the nephritis by introducing oxalates plus certain organisms, it is possible to produce in pregnant rabbits accidental hemorrhage, both external and concealed, and placental infarction. This method is successful in one hundred per cent. of cases. Hemorrhage could be produced, though less easily, by setting up an acute oxalate nephritis and then introducing organisms. A similar result could be obtained, also with less certainty, by producing an acute oxalate nephritis without subsequent introduction of organisms. A similar result can be obtained by setting up a chronic nephritis and afterwards introducing organisms. The latter first sets up an acute exacerbation, and hemorrhage occurs later.

In every case in which hemorrhage has so far been caused, an acute or subacute exacerbation of the nephritis, as indicated by a rise in the blood urea, has preceded the hemorrhage. The coliform group of organisms seems to be the most potent in producing the acute nephritis that predisposes to hemorrhage and infarction. An acute oxalate nephritis leads to a marked retention of urea, but even when the urea concentration in the blood is at its highest point no albumin may be present in the urine. It is important to bear this in mind before excluding nephritis in accidental hemorrhage.

These experiments show that nephritis, acute or chronic, is an important predisposing factor in the production of accidental hemorrhage and placental infarction, and that toxemia is the exciting cause. It is believed that organisms act only by setting up an acute exacerbation of the nephritis, and that they do not lead directly to the hemorrhage, the latter being caused by endogenous poisons held up in the circulation by the acutely damaged kidney.

Enucleation of the Ovum in Cæsarean Section.—C. Fournier (*Presse médicale,* April 3, 1926) recommends as routine procedure removal of the ovum intact, without rupture of the membranes, where labor has not yet set in. The operation should be performed as close as possible to term. The operating table should be horizontal. The uterus having been delivered through an incision eighteen centimetres long, the abdominal wall is in part held closed behind it with two hemostats which are crossed and fixed. Beginning at the top of the uterus a superficial median incision eighteen centimetres long is made in the organ with the tip of the scalpel. Three or four centimetres of this incision in its upper portion are then deepened cautiously with small strokes of the knife until the yellowish membranes are reached. The knife is now discarded, the left forefinger inserted between the uterine wall and membranes and the incision completed below and above with scissors. The intact ovum is next enucleated, both hands having been used in alternation to separate the sides of the ovum, as well as its lower pole, from the uterine wall. With slight pressure from below upward, the ovum emerges unbroken. Where the placenta is inserted anteriorly there is unusual bleeding as soon as the knife passes through the uterine wall. Under these conditions the hand is passed between the placenta and the uterus, whereupon the placenta emerges and the enucleation is conducted as before. An iodized compress is at once inserted into the cervix from above downward with long forceps. The intact ovum, carried to a table, is not ruptured for at least a minute, at which time the infant is ready for the first cry. During this interval, curiously, the placenta fails to bleed; there is continuous, spontaneous hemostasis, as if the infant continued to take all the blood from it; neither hemorrhage nor asphyxia is, therefore, to be feared. The procedure as a whole has the advantages of simplicity, cleanliness and neatness. It is aseptic, obviating the issue of amniotic fluid, which is sometimes contaminated or septic. The chief advantage, however, is that removal

of the membranes is facilitated. In the usual Cæsarean section, after extraction of the placenta there often remain débris of the placenta and especially of membranes on the lower segment. They are removed with a compress, but sometimes with difficulty, and some may remain. In the author's procedure, everything comes out with the intact ovum.

Vomiting of Pregnancy with Acetonemia.—Violet (*Presse médicale,* April 14, 1926) witnessed a case of severe vomiting in early pregnancy, accompanied by marked acetonemia. The embryo having died, previous to evacuation of the uterus the patient was given intensive alkaline treatment which brought about striking improvement and caused the severe abdominal pain and vomiting to disappear in a few hours.

Transperitoneal Cæsarean Section.—J. O. Polak (*Surgery, Gynecology and Obstetrics,* 42:4) describes an operative technic which, he asserts, has several advantages over the classical operation, though it cannot replace the Porro operation in infected cases. The technical points emphasized are: First, the low abdominal incision; second, the placing of the traction suture in the uterus at the upper limit of the abdominal incision which, when held taut, makes a perfect occlusion of the wound; third, the separation of the peritoneal flap, including the bladder; fourth, the delivery of the fetus by the head; fifth, the allowing of the placenta to separate spontaneously; sixth, the packing of the uterus with washed iodoform gauze to stimulate its contraction and retraction, this gauze being usually found in the vagina at the end of twenty-four hours; seventh, the complete occlusion of the uterine wound by the suture of the bladder reflexion over it which prevents the possibility of peritoneal leakage and intestinal adhesions.

Glycosuria and Pregnancy.—H. J. John (*Surgery, Ggnecology and Obstetrics,* 42:4) presents two cases showing the two contrasting findings in cases in which glycosuria is present in pregnancy. They show that the glycosuria in itself is but a symptom and is not of final diagnostic significance; but that it calls for further investigation. The first case required treatment for diabetes, while the second case did not require such treatment. On the one hand, to disregard the presence of sugar in the urine in such cases might mean that the patient would be deprived of a vitally needed protection; and on the other, to subject every such patient to the routine treatment for diabetes might mean a dietary restriction and a psychic strain which the patient could and should be spared.

Proliferative Gingivitis of Pregnancy.—S. Monash (*Surgery, Gynecology and Obstetrics,* 42:6) reports six cases in which tumorlike masses were observed forming on the gums of pregnant women. They began to form at a variable time during pregnancy, increased in size unless treated, and spontaneously diminished in size or disappeared completely after delivery. The growth, which attracts our attention because of its size, is not, as a rule, an isolated thing in these cases. It is usually accompanied by a generalized gingivitis and represents simply an exaggerated degree of this condition. The name proliferative gingivitis of pregnancy is proposed for all phases of the condition. This type of growth is inflammatory and should not be classed as a tumor. There is no gingivitis peculiar to and found only in pregnancy. A gingivitis practically identical with that described may be seen at times in men and in women who are not pregnant. Elimination of all irritating factors, and, if necessary, excision of the growth about a month or two after delivery, should constitute the treatment.

Pelvic Inflammatory Disease.—C. W. Hibbitt (*International Journal of Medicine and Surgery,* 39:4) recommends expectant and conservative management in acute and the majority of recurrent attacks in the therapy of this condition. Absolute rest is imperative, local external applications, enemata and sedatives give relief. Foreign proteins and actinic rays are worthy of trial. Surgical intervention is advisable in certain types and selected cases when serious manifestations are unduly persistent. The importance of ovarian conservation, especially in young women, cannot be overestimated. The important features here to be observed are: 1, Avoid damage to ovarian tissue; 2, relieve the ovary of complicating adhesions; 3, bring the ovary upward clear of adhesions and raw surfaces and keep it elevated; 4, preserve the ovarian blood supply.

Indications for Radiotherapy in Malignant Diseases of the Female Genitals.—Walter Fürst (*Schweizerische medizinische Wochenschrift,* April 10, 1926) differs in his views on the indications for radiotherapy by applying röentgenotherapy before resorting to surgical measures. In general, all malignant tumors are at first subjected to röntgenotherapy, and three weeks later their operability is determined at a laparotomy. In operable cases the extensive radical operation of Wertheim is carried out. If the histological examination of the specimen removed shows that the section was made in healthy tissue, the patients do not receive any more röntgen or radium irradiation. But if the operation was carried out in the midst of diseased tissue, secondary röntgen irradiation is given. The author has repeatedly observed cases of carcinoma which appeared to be inoperable on bimanual gynecological examination, but in which operation could be performed through healthy tissue after opening the abdomen. A suitable röntgen irradiation frequently acts remarkably well upon carcinomas in a purely symptomatic way; it reduces the size of the tumor and may even cause it to disappear entirely from the view in the speculum, and, furthermore, a preliminary irradiation eliminates the possibility of a subsequent postoperative peritonitis. After the biopsy, which is absolutely necessary for a definite diagnosis, immediate röntgen irradiation is added, and this in maximal doses. The operation should be done at least within three weeks after the preliminary irradiation. The latter should not be done on ambulant patients. With this technic the author reports some good results.

Blood Calcium in Eclampsia.—S. M. Feinberg and A. F. Lash (*Surgery, Gynecology and Obstetrics,* 42:2) find that though theoretically a decrease in the blood calcium may be expected in eclampsia, their research has proved unable to demonstrate any appreciable relation between the two. Determinations of blood calcium were made in cases of, 1, normal pregnancy, 2, preeclampsia and eclampsia, and 3, conditions simulating eclampsia. Although the figures for eclampsia were somewhat lower than those for normal pregnancy, the difference was negligible. Likewise, in several cases of pathological conditions simulating eclampsia clinically, the calcium figures were lower than those for eclampsia.

Corpus Luteum of Pregnancy.—D. Brannan and M. Cohen (*Surgery, Gynecology and Obstetrics,* 42:2) give two case histories which lead them to the conclusion that necrosis of the corpus luteum may occur in pernicious vomiting of pregnancy. It probably has the same significance here as necrosis of the liver and kidneys have in the same disease.

Psychic Disorders of Menstruation.—P. Bonifield (*International Journal of Medicine and Surgery,* 39:3) states that amenorrhea, menorrhagia and dysmenorrhea are frequently of purely psychic origin, and as such may for the most part be classed among the hysterias. Of the three, dysmenorrhea of psychic origin is by far the most common. The great majority of these cases, in fact, are of this nature. Because of over repression and under education of children on sex matters, menstruation, a primarily healthy physiological process, comes to be designated by the term "unwell." Often two or three reeducational conversations will bring about disappearance of pain. In other cases, where this simple form of treatment does not have the desired effect, if a psychological analysis be resorted to, and the unconscious conflicts on the phenomena of menstruation with their resulting tensions elucidated, the symptoms will be found to disappear entirely.

Fibromyomata of the Uterus.—F. A. Ford (*Surgery, Gynecology and Obstetrics,* 42:2) offers a comparative study of radiation and surgical treatment for this pathology, saying in conclusion:

In these unselected cases of fibromyomata of the uterus treated by operation and by radiotherapy, a relatively high percentage of the latter group has been found to require further treatment, either repeated radiation (eighteen per cent.) or operation (thirteen and seven tenths per cent.), as compared with four per cent. of the surgical group who received further treatment. It is true, however, that more recent cases, particularly after röntgenological treatment, are showing definitely better results through greater experience in the dose required. A study of individual cases shows so many thoroughly satisfactory results with radio-

therapy that the discrepancy in the total results must apparently be attributed to injudicious selection of cases, or to inadequate doses. Great care must be exercised to rule out malignant diseases at the time of radiation. Curettage should precede treatment in any case with suspicious symptoms. Inflammation, while apparently uninfluenced by radiation *per se*, as is shown by the lack of reaction to röntgen rays, is undoubtedly occasionally aggravated by the manipulation incident to the application of radium. Unusually hard fibromyomata containing extensive calcium deposits cannot be reduced satisfactorily by radiation; an incarcerated pelvic tumor is undoubtedly best removed surgically because of the inability to exclude adnexal disease. A röntgenogram may occasionally aid in detecting calcium deposits within a tumor.

The need of extreme care in excluding malignant disease is indicated by the fact that in six of the patients treated by radiotherapy a well established malignant process appeared within one year of the treatment. One other patient has probably malignant disease of the ovary, but refuses operation. Two others developed malignant disease within the two years after treatment, although in one case this may be considered a recurrence of the epithelioma in the abdominal wall at the time of radiation. In four patients, who remained free from symptoms for three years following treatment, malignant disease appeared. This may not be a higher percentage than that of pelvic malignant disease for all women at their age. However, it raises the question whether a focus of relatively devitalized tissue with altered blood supply may favor malignant change.

The Corpus Luteum.—C. G. Johnston and V. L. Gould (*Surgery, Gynecology and Obstetrics,* 42:2) concludes from their findings as follows.

1. Corpus luteum has been cited as the source of the hormone which produces hyperplasia of the genital tract and some authors maintain that extracts made by extracting corpus luteum with lipoid solvents are able to cause growth in the genital tract of certain mammals.

2. The amount of care exercised in collecting material is a factor which must be considered in order to be sure of the type of tissue obtained.

3. Using rats and rabbits we were unable to produce any noticeable changes in the genital tract by the injection of the alcohol, ether, acetone extract of carefully collected corpora lutea from pigs.

4. Pregnancy of the animals from which the corpora lutea were gathered, the size, consistency, or color of the corpora lutea had no effect on the results obtained.

5. Repeated positive tests have been obtained with the alcohol, ether, acetone extract of liquor folliculi of hog ovaries and in view of this are inclined to believe that the corpus luteum does not secrete the hormone which produces hyperplasia of the uterus and vagina.

Some Aspects of Ectopic Pregnancy.—C. S. Lane-Roberts (*Clinical Journal,* June 9, 1926) gives three main lines of treatment:

1, Expectant; 2, posterior colpotomy, and 3, abdominal section. These cases are often more or less confidently diagnosed as ectopic pregnancies, following abdominal pain, often some menstrual irregularity, vaginal hemorrhage, and the palpation of a definite pelvic or abdominal pelvic swelling. This swelling is limited, and of course there are no decided symptoms of continued internal hemorrhage. In other words, it is fairly certain that there is a pelvic hematocele, in all probability following an ectopic pregnancy, for which rest, with careful observation, may bring about absorption. If any evidence of relapse or of infection appears, more active treatment is indicated at once. The author considers such a line of treatment justifiable in some cases, for it may not be easy to have an abdominal section performed; the patient's own wishes may have to be studied, or she may be willing or prefer to lie up in bed for a considerable time. Apart from such circumstances it is probably best to have laparotomy done and the matter settled.

Some cases in this group definitely show a postuterine tumor due to hemorrhage, which may be treated by posterior colpotomy, with the verification of the diagnosis, and evacuation of the bloodclot and free blood, the cavity being packed, drained, and the plug changed daily. The vaginal incision closes only too easily, which should be prevented by the passage through of the gloved finger. Some cases are suitable for this treatment, though many appear later to discharge seropus for a considerable time, so that once more the abdominal route is generally preferred in most cases.

Definite hematocele cases will be treated by laparotomy—by far the most satisfactory method. By it the diagnosis is at once confirmed, any coexisting tubal ovarian or appendicular trouble dealt with at once, and any chance of relapse more satisfactorily dealt with.

On the whole, the results of cases of ectopic pregnancy treated by laparotomy are satisfactory, even if the patient is almost pulseless at the time. The interstitial ruptured ectopic pregnancy may complicate matters, as, owing to the situation of the vessels of supply, it may be necessary to do a subtotal hysterectomy in order to control the hemorrhage. Reinfusion of the mother's blood has been advocated in severe cases. The blood from the abdomen is scooped up in a cup, strained through double muslin, diluted with saline solution in a strength of three to two, and reinfused through the median basilic vein. But presentday opinion is against this method, though successful cases have been reported. The procedure takes much time and involves much shock, and the desperate cases are much the better for the least amount of handling. Again, such blood is defibrinated, and has no further value in inducing coagulation. Probably by leaving this defibrinated fluid blood undisturbed, it is absorbed quite rapidly from the peritoneum. The treatment of election for a bad case is immediate laparotomy, immediate hemostasis of the bleeding points, as rapid closure of the abdomen as possible, and if possible immediate whole blood transfusion from a suitable donor.

Treatment of Severe and Persistent Uterine Hemorrhage by Radium.—Sidney Forsdike (*British Medical Journal,* March 13, 1926) reports his favorable results in two hundred cases of a type of hemorrhage which is frequently described as idiopathic or essential hemorrhage, pathologically referred to as chronic metritis, fibrosis uteri, or chronic subinvolution. However debatable the pathology, the one distinctive feature is the excessive and uncontrollable hemorrhage with absence of any pelvic lesion to account for it. This series includes only those cases that have proved refractory to drugs and a single curettage.

Clinically, two types of uterus are met with in this condition—the systolic and the diastolic. The diagnosis must necessarily depend upon the result of an exploratory curettage, the exclusion of new growth, the absence of any other pelvic lesion which would induce hemorrhage, and upon the physical characters of the uterus as determined bimanually and by the curette.

Various methods have been described, namely, placing the radium in the uterus, vagina, and upon the abdominal wall. The latter method has been practically abandoned. Prolonged exposures in the vagina are fraught with the danger of fistula formation. The results from radium *in utero* are so constant and satisfactory as to place other methods which are open to criticism beyond the scope of clinical practice.

Anesthesia is required for an imperative exploration of the uterus, and the radium is introduced at the same time. In all cases dilatation of the cervix is done, and any tissue removed is referred for microscopic examination. The radium is screened in brass or lead and the tube is then surrounded with rubber tubing two to three mm. thick to exclude secondary rays. The bladder is maintained empty by a selfretaining catheter. The vagina is plugged with gauze soaked in liquid paraffin to keep the radium in place and to protect the rectum.

The dose must be individualized. The menopause cases were given 100 mg. of radium bromide for twenty-four hours and one exposure was found to be enough in 128 cases. Late recurrences occasionally were seen. Cases of fibroids were exposed for thirty hours, and a second treatment was rarely required. In young women smaller doses were used.

The symptoms during and following the exposure include pains, vomiting, fever, hemorrhage and leucorrhea. Painful micturition is frequently observed after the treatment.

The sole absolute contraindication to the use of radium in this condition is the presence of pelvic inflammation. Relative contraindications are patient bled white through loss of blood.

Chief among the causes of bleeding some months after the amenorrhea are septic foci, pyorrhea, etc.; cystic ovaries; pelvic inflammations; high blood pressure associated with contracted kidneys.

Psychogenesis of Leucorrhea.—W. von Arx (*Schweizerische medizinische Wochenschrift,* March 20, 1926) maintains that leucorrhea is a bodily physical symptom, the result of a purely functional transmission of a psychic conflict; at the same time it is also the transformation of a psychic conflict into the physical. It is a resistance reaction.

Much may be accomplished with psychoanalysis in these cases. The sexual life of these patients requires careful investigation. Frequently there is a history of coitus interruptus, ejaculatio precox, impotence, etc., in the male, which should and can often be corrected. A large number of these cases belong to the group of neurosis, which may show all grades and transitions from the lightest forms to the most severe, the compulsion neuroses and the fixed neuroses (psychoses).

Retroposition of the Uterus.—J. F. McGrath (*Surgery, Gynecology and Obstetrics,* 42:2) holds that congenital retroposition is rarely symptom productive and therefore it seldom requires treatment. Symptom productive retroposition of the uterus of the acquired type is most common among women who have been pregnant. Symptom productive retroposition will show on careful examination associated conditions, and the diagnosis will quite certainly be confirmed at operation. More efficient and extended postpartum observation and care will greatly lessen the incidence of acquired retroposition. The vaginal pessary when properly used is an instrument of undoubted value and should be more frequently used to promote proper postpartum involution. Any operation that carries with it the risk of intestinal obstruction or uterine dystocia should be condemned. The Simpson-Montgomery technic with proper care of associated defects offers the best prospect of cure. In a few selected cases the Baldy-Webster technic is superior.

Secretion of Colostrum in Pregnancy and Gynecological Diseases.—Ludwig Ballin (*Zentralblatt für Gynakologie,* January 30, 1926) reports that up to the fifth month of pregnancy the secretion of colostrum cannot be utilized as a diagnostic sign of pregnancy. Women, who have gone through abortions and births, especially those who have nursed babies for a long time, may show a breast that secretes either milk or colostrum for years (up to twenty-five per cent. in the author's cases). It was also found that inflammatory processes in the female genitals may produce lactation of the breast. Changes in the ovary, such as lead to its loss or diminution of function, especially in the climacterium, may likewise cause a pathological secretion in the breast. The secretion of the breast in spurious pregnancy during early years cannot definitely be attributed to aplasia or hypoplasia of the genitals or ovaries; in the later years, on the other hand, aside from the psychic condition of the patient, the changes that produce the climacterium in the ovaries, play some part.

The author recommends that the examination of the breast for pathological secretion should become a habit when determining the physical condition of female patients. Only then could it be possible to undertake investigations to determine whether the secretion of the female breast has any relationship with the internal, psychic and gynecological diseases.

The Effect of Thymus Extract Upon Uterine Activity and Its Practical Application in Obstetrics.—Nikolaus Temesváry (*Zentralblatt für Gynäkologie,* February 6, 1926) has administered several preparations of combined hypophyseal and thymus extract, which as a result of their hypophyseal effect upon contractions of the uterus and of their thymus effect, act specifically to relieve exhaustion, with great benefit in all cases in which it was properly applied. Its use is indicated less in miscarriages or premature births and during the puerperal period than during labors that are already in progress. In order to obtain a satisfactory effect true labor pains must be already present. No injurious effect either upon the mother or child was observed. The variation in blood pressure was no greater than after the use of pure hypophyseal extract. The mothers never complained of any symptoms and almost all the children were born without asphyxia.

The advantage of these preparations is that they are entirely harmless, which is not the case with hypophyseal extracts. With the author's preparation the act of labor was accelerated, and in contrast to the hypophyseal extracts, with which there frequently occurs a "secondary relaxation of the uterine musculature in the third stage of labor," the placenta was expelled shortly after the birth of the fetus through the continued action of the labor pains and the effect carried over into the third stage of labor. Postpartum hemorrhages were also not observed.

The contraindications for this preparation are the same as for the simple hypophyseal extract, and include a markedly contracted pelvis and disproportion between the size of the pelvis and that of the fetal head, transverse position of the fetus, false presentation of the advancing fetal part, fetal malformations, developmental anomalies of the uterus and vagina, the formation of a contraction ring, and diseases of the heart and kidneys.

Utility of the Erythrocyte Sedimentation Test in Gynecology.—O. Silzer (*Zentralblatt für Gynäkologie,* February 6, 1926) asserts that an operation for inflammatory adnexal tumors is indicated when the sedimentation time is less than ninety minutes. In the differential diagnosis between tubal pregnancy without severe hemorrhage and inflammatory tumors the erythrocyte sedimentation test is of value in a negative way, in so far as it may be said, with a fair certainty, that sedimentation values of less than fifty minutes speak in favor of adnexal diseases. In rare cases a differential diagnosis between an advanced pregnancy and a soft myoma of the uterus is possible with this test. In carcinoma, initial cases still show normal sedimentation periods, but in advanced cases there is a pathological acceleration of sedimentation in proportion to the severity of the disease. Benign tumors and noninflammatory diseases of the genitals show normal sedimentation periods.

Significance of the Erythrocyte Sedimentation Test in Gynecology.—G. Frommolt and L. Motiloff (*Zentralblatt für Gynäkologie,* February 6, 1926) believe that the erythrocyte sedimentation test is of value in the following gynecological conditions:

1. In clinically benign, noninflammatory tumors and in changes of position an acceleration of the sedimentation less than sixty minutes indicates the search for the cause of this acceleration. If it is not found in intercurrent diseases and if such exceptional causes as anemia, torsion of a pedicle and decubitus ulcer can be eliminated, one should be prepared for surprises at the operation.
2. In inflammatory diseases it is necessary to avoid an operation when the sedimentation reaction takes less than sixty minutes.
3. In the diagnosis of extrauterine pregnancy the absence of a correspondence between acute and recent beginning of the disease and the acceleration of the sedimentation is valuable except in tubal rupture with marked anemia.
4. In carcinoma the chief value of the sedimentation test lies in the early recognition of a recurrence through the reappearance of an accelerated sedimentation test. The accelerated sedimentation may be utilized in the diagnosis of carcinoma of the ovary in contrast to the past history.

MALIGNANT DISEASE

Use of Lead Colloids in the Treatment of Cancer.—Frank Coke and J. B. Cook (*British Medical Journal,* March 6, 1926) relate their experiences with a combination of lead with a very complex radicle of high molecular weight, containing mercury in the same proportion as the lead, but in a nonionized form, called "lead M.A.," the M denoting mercury and the A an amino group. The colloidal suspension if lead M.A. contains 0.1 per cent. of mercury and 0.1 per cent. of lead. Of three such preparations, this gives the best results and it was tried out in twenty inoperable cases. The results can be divided into four groups.

The first group comprises those patients on whom the lead did not appear to have made the slightest difference. In the second group temporary improvement was shown, as manifested by the patient's weight remaining stationary for many months or even gaining, a decrease in the size of the growth and the lymph glands. In the third group of two rather peculiar cases, the cancer seemed to abort, the whole of the growth apparently falling out. The fourth group comprises cases that were cured by means of both röntgenotherapy and the lead treatment, it being difficult to determine which form of treatment was the most effective.

During the treatment, full blood counts must be made in all cases, and stippled cells must be frequently sought for. Uranalysis is essential when giving full doses. Protein

shock has occurred occasionally a few hours after an injection. The injections may be made intramuscularly or intravenously.

In the series of cases reported the dose was on the whole small. There is a large margin of safety within which injections of lead can be increased in size and frequency before toxic symptoms from the lead need be expected. But the dosing in any particular case will depend upon a great many different factors. Patients of large weight with no cachexia will require large doses. Males will take larger doses than females. Emaciated patients and those with growths which have ulcerated to the surface will require small doses, at any rate to commence with. As any growth may abort, special care must be taken to make such abortion as aseptic as possible. In growths of the gut abortion must be particularly guarded against.

Arrangements have been made whereby a supply of lead M.A. will be available for general use.

Treatment of Malignant Disease with Lead.—W. Blair Bell, H. F. Woolfenden, W. R. Williams, L. Cunningham, S. B. Herd and J. G. Adami (*Lancet,* March 13, 1926), state that the treatment of 227 cancer patients was largely experimental and clinical and of a tentative nature, and that, as might be expected, the results were uneven and the failures and misfortunes many. They make no claims whatsoever in regard to the general curability of cancer by the use of lead.

The results of treatment of malignant growths with preparations of lead add further testimony in support of our views of the nature of malignant neoplasms. Much work remains to be done in regard to the discovery of a more therapeutically active preparation of lead, which is at the same time less toxic generally. All types of malignant growths are probably amenable to the beneficial influence of lead, provided the metal can reach the malignant cells in sufficient quantity. Adjuvant surgical and radiological measures in suitable circumstances may be employed with considerable advantage. When the growth has been partly, or apparently entirely, removed, intravenous injections of lead should be employed within a few days of the operation when possible. The method of treatment is difficult, and to some extent dangerous, and can only be safely employed by those who are thoroughly experienced in the work, and have laboratory facilities at their disposal.

J. G. Adami records the impressions left upon him by this series of cases as follows: 1. The healthy, the indeed almost florid appearance of the majority of the patients. There was complete absence of cachexia, and also any evidence of plumbic anemia. 2. Absence of wrist drop or other sign of lead poisoning; only one patient complained of some dimness of vision. 3. The rise in weight and good bodily condition of the majority, and, with this, their repeated testimony to the fact that they were now actively at work at their usual vocations. 4. The absence of evidence of recurrence. The problem evidently resolves itself into this: What is the dose of lead which will surely kill off all the cancer cells without inflicting too grave an injury upon the other tissues of the body? 5. The reduction of the mortality to sixty per cent. or even seventy per cent. is a material reduction upon, say, ninety-five per cent. Lead treatment is an important step forward in the direction of ultimate control of what is one of the gravest ills which inflict mankind.

The New Outlook on Cancer.—W. Cramer (*British Medical Journal,* January 30, 1926), states that in so far as Gye's conception of cancer is based on experimental work, it has to stand the test of experimental confirmation, but it has given us a new outlook on cancer. His conception explains that the aimless, lawless, irresistible growth is the result of a virus entering into a few cells and impelling them to grow, freed from the control and inhibition which regulate the growth of the normal cell. The cell with the virus nevertheless retains its biological character as a cell of the species, of the tissue, and of the individual to which it belongs; hence the limitation in transmission and the fact that the cells of a neoplasm breed true. The virus is common to the tumors of different species and classes of animals; hence the wide zoological distribution of the disease. The virus of itself is nonpathogenic; that explains why the disease is not contagious. The virus can only enter a cell if some accessory biological factor is present; such a condition can be induced by very different forms of chronic irritation; hence the local origin of the disease. We can also understand why agencies so different as tar, x rays, and animal parasites are capable of inducing cancer. Under exceptional conditions the parenchyma of a carcinoma may have such an effect on the cells of its stroma that the virus is able to infect the connective tissue cells and a sarcoma arises from a carcinoma. The cells of some very rapidly growing and highly malignant tumors produce in abundance a substance which will act as an accessory biological factor, but only for the same type of cell as the one of which the tumor is composed. Such a tumor can therefore be transmitted by a cell free filtrate containing both the virus and the specific factor. Other tumors contain less of this specific factor or it is more labile; they can therefore only be transmitted by living cells. There is therefore no fundamental distinction between these two type of neoplasms, as was hitherto supposed; they differ only in degree.

These differences in the amount of the specific factor present in different tumors affords an explanation of the variations in the clinical behavior of different neoplasms as regards rate of growth and malignancy. A tumor forming an abundance of the specific factor will grow rapidly and metastasize rapidly, because in such an extreme case the tumor will grow, not only by cell division, but also by a transformation of the normal cell of the same type. This would explain the fulminating growth of some types of cancer in the human subject. Tumors containing less of this specific factor or forming a less stable specific factor will grow more slowly and metastasize less rapidly. The striking fact that the growth of a neoplasm is independent of the nutrition of the animal in which it grows calls for an explanation which places the impulse to grow within the cancer cell. This is obviously in accord with the conception that the growth of a cancer cell is due to an intracellular virus assisted by a chemical factor elaborated by the tumor cells.

Gye's work raises many new problems, but it has solved our old and fundamental difficulties. Its particular merit is that it is not in conflict with any of the previously established facts, but, on the contrary, it confirms them. Taking them as his starting point, he has just gone one step further, and in doing so he has hit upon a conception which links together all our knowledge concerning cancer, which removes all the apparent contradictions, and which explains all the essential features of the disease. It is the first adequate explanation of the causation and growth of cancer, and it points the way to further progress.

Clinical Experiences with Carcinoma Antitoxin.—M. J. Scott (*Journal of Cancer,* January, 1926) draws the following conclusions from his clinical experience in the use of Glover's carcinoma antitoxin:

1. The antitoxin has a selective action for carcinoma, as frequently evidenced by the sensation of heat or slight pain, tingling, and sometimes by discoloration and swelling, in practically all carcinomatous tissue shortly following the subcutaneous, intramuscular or intravenous injection of the antitoxin.

2. In several instances, where tissue from lesions had been mircroscopically diagnosed as carcinomatous by competent pathologists, the author had the opportunity to make further microcopic examination after the administration of several treatments of antitoxin, and found instead of carcinomatous tissue, a broken down, degenerated tissue mass.

3. Shortly following the injection of antitoxin, any hemorrhage, foul smelling discharge and the pain resulting from the carcinoma, not that due to impingement of nerves by scar tissue, were considerably lessened in the majority of cases. In open lesions a discharge of serous fluid, sometimes tinged with more or less blood, followed in from one to several days.

4. Where the location of the size of the lesion had caused partial obstruction in any part of the alimentary tract, with accompanying symptoms—discomfort, pain, distention—relief from these conditions was usually obtained quickly; this even in cases with carcinomata too far advanced to expect complete recovery.

5. In cases where the administration of the antitoxin was followed by a rapid breaking down of the carcinoma and an absorption of this broken down tissue, patients often became toxic, developed a leucopenia and began to "lose ground" much as do similar cases after large doses of radiation. By suspending treatment temporarily, stimulating elimination, and adopting measures to correct the blood picture these patients were usually started "upgrade" again.

6. The administration of the antitoxin, more especially in advanced cases where large growths may be broken down too quickly, must be carefully regulated according to clinical results, laboratory tests and clinical experience.

7. Beyond a certain dose, which varies according to the location and the extent of the lesion and the patient's general condition, no increase in the amount of antitoxin administered, either by increasing the dose or by shortening the intervals between doses, is of any perceptible benefit to the patient, and in some cases may be a great detriment.

8. Each patient's general condition should be watched closely at all times and especially should complete urine and blood examinations be made frequently, though frequent examinations and manipulations of carcinomatous lesions should be avoided as they are harmful.

9. As in the treatment of any disease by any specific remedy, all other measures available that will assist the patient should be adopted—proper removal or destruction of cancerous mass when practical, and the adoption of such measures as will increase the patient's resistance and vitality.

10. In the more advanced cases with large primary growths or large metastatic masses we find that it is best to remove as much as possible of the masses by cautery (preferably) or surgery following radiation in suitable cases, and then treat any remaining invasions or metastases by the administration of antitoxin. This removal of the mass is done for three purposes: To avoid the necessity for the injection of the amount of antitoxin that would be required, or the necessity for the patient to produce sufficient antibodies, to break down the carcinomatous mass; to avoid the necessity for the system to absorb the broken-down tissue if not removed, and to avoid the protein poisoning of the patient, which would follow such absorption; and to avoid the overload that would be thrown on the kidneys and other organs of elimination if this mass were allowed to remain and be broken down and absorbed.

11. Treatment in a general hospital is better than outside of it, but only in a specialized institution can best results be expected.

12. When given early in the course of the carcinomatous infection, with patients whose general vitality and resistance are good and before the patient has absorbed much toxin, the chances for complete recovery are good; the lesions at first usually becoming slightly larger and much softer, then being gradually absorbed. Given later, when the lesion is more extensive and metastases are present and the patient is quite toxic, or in patients whose vitality and resistance have been lessened, but not destroyed by other causes, the chances for complete recovery are variable. When given still later, where general carcinomatosis is present or where an extreme amount of toxin has been absorbed, or with patients of very advanced years and low recuperative powers, or whose vitality and resistance have been greatly lessened by any other cause, the chances for complete recovery are extremely small, and little is to be expected beyond making the patient's conditions less intolerable.

13. There are marked differences in the degrees of virulence of the organism and also marked differences in the rsistance of different patients to the disease.

14. The antitoxin is not considered a "cancer cure," nor is it claimed to be such by Glover, but it is an entirely logical, and, in at least some instances, an effective treatment for carcinoma.

Endothermy in Carcinoma of the Tongue.—G A. Wyeth (*Annals of Surgery,* 83:5) says:

Our confidence in endothermy as a treatment for the removal of malignant lesions of the oral cavity, and our belief that better results will be achieved in the treatment of all neoplasms when endothermy is employed in the beginning in all those cases to which it is applicable, are based upon the record made by the method over a period of five years, a record made upon cases referred for treatment in many instances after surgery and physical measures—one or both—had failed. It is after careful consideration of the admirable results achieved by proper endothermic procedure that we affirm that endothermy should be given the preference in treating malignant lesions of the oral cavity. We enumerate the following explicit reasons for our belief:

1. By endothermy the extent of the destructive process is definitely under the control of the operator.

2. The effect of endothermy's destruction is immediate. The operator is not obliged to wait many weeks to determine just what has been accomplished by the forces he has set in motion.

3. Treatment by endothermy is followed by immediate cessation of pain. Sensory nerves are severed and capped.

4. This capping of nerves tends to eliminate surgical shock.

5. There is no postoperative reaction, and the patient is able to return immediately to normal diet.

6. There is no hemorrhage. The operator is spared the need of working in a field obscured by blood.

7. No other method offers endothermy's protection against the danger of recurrence and the threat of metastasis. The technic which isolates the malignancy, before its removal as dead tissue, by a path of protective destruction drawn in healthy tissue, and which thereby seals lymphatics to and from the affected part, is peculiar to endothermy.

8. Endothermy can be used in repeated treatments without prejudice to the patient. This is because lesion treated is destroyed and removed in a single operation without injury to surrounding tissue. The appearance of subsequent nodule or induration can be met with destruction and removal on precisely the same terms as the first lesion, if endothermy is the remedial agent.

For any and all of these reasons endothermy should be given the precedence in the treatment of cases of malignancy of the buccal surfaces.

Carcinoma of the Penis and Endothermy.—H. A. Kelly and G. E. Ward (*Surgery, Gynecology and Obstetrics,* 42:5) find that with proper technic (coagulation) the local lesion in carcinoma of the penis can be cured with endothermy. It is possible to eliminate a metastatic gland by incising the skin and exposing it and treating it with the strong bipolar coagulating current destroying the whole interior of the gland. This is an exceedingly important principle capable of a wide application in the treatment of lesions occurring in the abdomen, neck, and elsewhere in the body. For example, in intraabdominal malignancy with glandular metastases, it will be easy to insert the needle carrying a high frequency current and almost literally explode diseased glands out of existence, leaving the dead tissue to be absorbed *in situ.* This method of actually removing diseased lymphatic glands without long and tedious dissection with consequent danger to the patient is a tremendous adjunct to our surgical technic.

Cancer of Bladder Treated Two and One Half Years by Radium.—Reynard and Nogier (*Presse médicale,* April 14, 1926) report the case of a woman in whom radium had been used two and one half years previously for a histologically verified cancer of the bladder. This was followed by ten x ray exposures. Recovery is still maintained. The anterior wall, severely infiltrated at the time of the radium treatment, is now soft. A single deep x ray exposure caused a nodule which appeared in the anterior wall five months later to disappear. Cystoscopy hardly shows the area of implantation. The favorable results are ascribed to the exact apposition and perfect fixation of the radium during the treatment, and also to the use of highly penetrating x rays with long focal distance which permitted of the administration over the entire vesical mucosa of a considerable dose of the rays and of bringing the action of radium to completion over a larger area.

Technic of Use of Removable Radon Seeds in Carcinoma of the Tongue.—Joseph Muir (*Annals of Surgery,* May, 1926), describes in detail a new technic of radium therapy in lingual carcinoma which offers a practical means of irradiating even the most inaccessible tongue lesions. This is accomplished by the implantation of removable platinum radon seeds. As the methods of treatment heretofore used have always proved unsatisfactory, this article is of especial importance from a clinical view point.

The various methods by which lingual carcinoma has previously been treated are discussed and their advantages and drawbacks considered. Imbedding of bare tubes according to Janeway's method affords an even distribution of radiation, but causes necrosis which is invariably followed by sloughing and may even induce unavoidable, fatal hemorrhage. If screened seeds are used, necrosis is avoided, but they are objectionable because they must remain in the tongue as foreign bodies. The platinum needles advocated by Regaud also obviate necrosis and can be removed when radiation has been accomplished, but proper distribution of these applicators is difficult; they cause too much trauma; and above all, they are hard to immobilize and cannot be placed upon the posterior dorsal surface of the tongue.

The method offered in this article obviates all these difficulties, while retaining every desirable feature. The seeds

are completely screened with platinum, thus doing away with necrosis and sloughing; they are easily withdrawn after an adequate dose has been delivered, so that they do not remain in the tissue as foreign bodies. These seeds can be placd in any position required, just as readily in the hitherto inaccessible root of the tongue, as in more favorable positions. The article is profusely illustrated, demonstrating the exact method of approach to these inaccessible lesions.

The growth is first carefully palpated, and the number of seeds required determined according to its depth and surface extent. When a seed has been placed in the desired position, the attached thread is left protruding from the point of entry, where it is cut off so as to leave just enough to be readily grasped with forceps at the time of removal.

The entire treatment causes no pain, and but slight inconvenience to the patient; and when skillfully performed under proper aseptic precautions, the technic offers an excellent means of solving one of the most vexing of clinical problems.

Cancer of Paranasal Sinuses.—D. Quick (*Surgery, Gynecology and Obstetrics,* 42:4), emphasizes the following facts. Surgical exploration of the paranasal sinuses and biopsy should be resorted to earlier and more frequently so that earlier diagnosis of new growths may be made. With few exceptions, the principles applying to surgical removal of cancer in general cannot be carried out in dealing with growths in the paranasalsinuses. Radium and x rays are of value in treating this group of cases but, except in palliative procedures, must be used in conjunction with surgery. Radium and x rays may be depended upon to eradicate the tumor tissue if applied accurately and uniformly throughout the growth in sufficient doses. Surgery must be employed to provide exposure for radium application and adequate drainage. The anatomical relations of the parts are such that infection is a much greater menace here than in new growths in most other locations.

The Axilla in Cancer of the Breast.—I. E. Jennings (*Annals of Surgery,* 83:6) points out that in many cases of advanced cancer of the breast the skin of the axilla is found involved. In a smaller number of advancing cases early and low involvement can be detected. It is logical to suppose a microscopic invasion in comparatively early cases. It is the custom to ignore this fact and to plan incisions for the radical cure of cancer which invade, cross or dissect the skin and superficial fascia of the lower and middle axilla. The scars of such transaxillary incisions are frequently the site of local recurrence and it is fair to suppose that a wider dissemination of the disease has been favored by such an operation.

An operation is offered in which the skin incision surrounds the skin of the axilla and in which the axillary skin, fascia and glands are removed en bloc with the pectoral muscles and a wide area of deep fascia. The cicatrix of this operation does not limit the motion of the arm.

It is recognized as a general principle that attempts at radical surgery of cancer of the breast should be planned to completely surround the disease. This operation is offered as a more complete compliance with this demand.

Esophageal Carcinoma.—M. C. Myerson (*American Journal of Surgery,* 40:3) advocates the intubation of the esophagus after a sufficient space has been made for the placement of a tube. The technic is outlined as follows:

On the day before the operation the patient is given five or six yards of button hole twist "D" to swallow. After preliminary fluoroscopic and röntgenologic study, esophagoscopy is performed and a threaded bougie is passed to ascertain the exact upper limit of the constriction. This is of value later in ascertaining the proper placement of the silver tube. The Plummer bougies are now introduced over the string and the stricture is dilated. When the esophagoscope will no longer permit the passage through of the next larger bougie, the esophagoscope is withdrawn and dilation carried out with the string as the only guide. This is perfectly safe for by now a lumen permitting the passage of thirty F. bougie has been established. After dilatation to a forty-five F. measurement, the intubation tube is dropped into the esophagus either ahead of the esophagoscope or through it and it is implanted into the dilated area.

The patient is shortly after referred for fluoroscopic and röntgenological study to conform the proper placement of the tube.

The tube usually stays in place very well. It may become dislodged or the neoplasm may extend above or below its limits. In such a case esophagoscopy and proper adjustment of the tube becomes advisable. The tube does not seem to ulcerate. It seems rather to canalize the growth and is held in place by the infiltrative process. The possibility of splitting the esophagus is a remote one, and it is my feeling that bouginage, when done in the earlier stages and under esophagoscopic guidance, is quite safe. The tube becomes black but that does not seem to matter. Patients are advised to follow the semisolid food which they may swallow with small drinks of fluid.

These tubes may stay in place indefinitely, and are in no way uncomfortable to the patient. He can now sit at the table and eat as before. He needs no special nursing care, he has no postoperative wound, is out of the hospital at the end of forty-eight or seventy-two hours, and is still utilizing his natural passages for the ingestion of his food.

Bacterial Flora of Cancer of the Breast.—Stafford L. Warren (*American Journal of the Medical Sciences,* June, 1926) says that micrococci and diphtheroids have been cultured readily from cancer tissue obtained from seven human breasts, without obvious areas of infection. They also were present in a breast with chronic mastitis and in parts of a breast not involved by cancer.

It would appear that these organisms are casual inhabitants of the breast structures, and play no direct part in the production of cancer of the breast.

Observations on Cancer.—L. Frank (*International Journal of Medicine and Surgery,* 39:3) feels that all malignant neoplasms should be surgically removed as widely as possible where there are no definite contraindications. There are, of course, cases where radium may be used to advantage, and others in which the growth should be removed by the scalpel alone. In the cervix we have the ideal place for the treatment of malignancy with radium. However, in carcinoma of the lip, tongue and mouth where the glands are usually involved, it is probably a mistake to treat by radium without block dissection. Preoperative treatment of carcinoma for the purpose of blocking lymph drainage with either radium of the röntgen ray is of no value.

Somatic Origin of Malignant Disease.—C. R. Crowther (*British Medical Journal,* January 23, 1926) believes that malignancy is not a property of cancerous tumors, but a suicidal reaction of the body to an innocent hyperplasia. The reaction is suicidal because the hyperplastic cells are really a part of the body, and the specific poisons generated to destroy the tumor are almost equally poisonous to the body at large. Sarcoma probably differs in its nature from carcinoma; here the diseased process seems more complex, but the essential nature of malignancy is probably the same. It follows that if the body can be led to disregard the tumor the malignant process will stop, and the patient will be cured, save that the original hyperplasia will remain. It seems possible that this result may be achieved by blocking the afferent nerves of the part.

Radiodiathermy in the Treatment of Inoperable Malignant Disease of the Upper Air and Food Passages.—William Milligan (*British Medical Journal,* February 27, 1926) summarizes the advantages of diathermy as follows:

1. It is of definite value when ordinary surgical procedures are contraindicated. 2. It is followed by little, if any, shock. 3. With reasonable care it is a practically bloodless operation. 4. Besides sterilizing the tissues it blocks the vascular and lymphatic channels leading to and from the growth. 5. By so doing it tends to prevent dissemination of the cancer cell. 6. It affords relief from mechanical symptoms, such as obstruction and dyspnea. 7. It arrests the tendency to spontaneous hemorrhage. 8. It relieves pain. 9. The resulting scar tissue is soft and pliable and does not form adhesions. 10. Septic bronchopneumonia is less frequent than after severe cutting operations.

Its disadvantages are: 1. It destroys a certain area of healthy tissue around the original growth. 2. The walls of blood vessels in the immediate neighborhood of the growth may become softened and ulcerated, with resulting attacks of severe secondary hemorrhage. 3. When the skin is involved keloid cicatrices may develop.

The advantage of combining the application of radium with coagulation by diathermy is that the lymphatic area is thereby irradiated, wandering malignant cells are killed off, and the risk of subsequent metastasis is materially lessened.

The results obtained by radiodiathermy will repay all the trouble taken.

OCCUPATIONAL DISEASES—ANILINE POISONING

In a claim by the employee of a fur dyeing company suffering from dermatitis, the claimant contended that he suffered from aniline poisoning, a disease provided for in the New York Workmen's Compensation Law, section 3, group 19, subd. 2, No. 8, if contracted while engaged in a process involving the use of aniline. It appeared that the claimant did not work in his employer's department where the workmen applied the aniline dyes to the furs, but handled and brushed dry furs after the process of dyeing was complete. It was held that claimant, not having been engaged in applying the dyes, was not within the coverage of the subdivision, and was not suffering from an occupational disease. Sokol v. Stein Fur Dyeing Co., 216 N. Y. S. 167.

CITY HOSPITAL EMPLOYEE INJURED ON HOSPITAL PREMISES HELD ENTITLED TO COMPENSATION

A nurse in a city hospital situated on an island owned by the city and occupied entirely by city institutions, after completing her work for the day, prepared to leave the island to go to the city. While on her way from the nurses' home, she fell on a sidewalk which was the proper passageway for her to take. The accident was due to the fact that snow had not been cleared off the walk. The New York Court of Appeals holds, Lynch v. City of New York, 252 N. Y., 115, 151 N. E., 159, that she was entitled to compensation under the Workmen's Compensation Law. Her employment did not cease when she left the hospital, but continued while she was on the island, leaving and returning thereto over the route provided by the employer for such purpose, the customary and practical way of ingress and egress; the employment exposing her to the hazards of the way in and out. This rule would not, of course, apply to all the sidewalks of a city over which city employees might pass on their way to and from their work.

TAKING X RAY PICTURE AND EXPLAINING IT NOT DIAGNOSIS

Section 107 of the Sanitary Code of the city of New York provides: "No person shall maintain, operate or conduct an x ray laboratory . . . wherein radiographs are taken, diagnoses made or human beings examined or treated by x rays, without a permit therefor issued by the Board of Health, or otherwise than in accordance with the terms of said permit and with the regulations of the said Board." Supplementary to this sction the board adopted a regulation providing: "Every x ray laboratory shall at all times be in charge and under the direction of a duly licensed physician or other person whose knowledge, experience and qualifications to operate and use an x ray machine are satisfactory to the Health Department." The New York Court of Appeals holds, Matter of Sausser v. Dept. of Health, 242 N. Y. 66, 150 N. E. 603, reversing 212 App. Div., 872, that the department may not arbitrarily reject the application of a concededly experienced and skilled x ray photographer for a limited permit to take radiographs, on the theory that he proposes to explain what the pictures show and consequently to diagnose and treat diseases. It is held that taking an x ray photograph and explaining what it shows do not constitute diagnosis or treatment. "It may be conceded," the court says, "that the reading of an x ray photograph would be a slight and necessary step in diagnosis and treatment, but it would fall far short of what we understand by those terms, which comprehend not only knowledge of a certain condition such as would be shown by the x ray photograph but, beyond that, medical or surgical consideration of what may have caused the condition presented to the eye and of the treatment which ought to be given to it."

INSUFFICIENT EVIDENCE FOR SUBMISSION TO JURY ON ISSUES OF NEGLIGENCE

In an action for malpractice when employed to attend the plaintiff for a fracture of the femur of the right leg, the questions on appeal were, the sufficiency of the evidence to require its submission to the jury on charges of negligence in diagnosis and treatment, especially in a failure to use x ray to aid diagnosis, and in burning the flesh of the leg by hot applications. The method of treatment was by Buck's extension. It was charged that the defendant failed to ascertain the exact location of the fracture. The Wyoming Supreme Court held, Wright v. Conway, 241 Pac., 369, that there was no substantial evidence to sustain this charge. On such a question, involving a highly specialized art, with respect to which a layman has no knowledge, the court and jury must depend on expert evidence, and in the absence of such evidence there is nothing to justify submitting the issue to the jury.

Evidence was also lacking to show that the extension as applied was in any way a proximate cause of the alleged failure to maintain apposition or the alleged resulting injury. Having correctly ascertained the location and nature of the fracture, an x ray picture for that purpose was held to be unnecessary.

Failure to secure a union of the bones during the period of treatment, or even longer had it been continued, would not alone, it was held, establish negligence, or even be a ground for an inference thereof, since a successful result is not guaranteed.

The failure to use an x ray has apparently never been held to be negligence when it did not directly appear that such an instrument was available, and it was held that the burden was on the plaintiff to show this.

As to the charge of burning plaintiff by hot applications, it did not appear that the defendant did more than to suggest or prescribe the hot applications. It was not shown that he applied them, or that he was present when they were applied. If applied by a nurse at the hospital, there was nothing to show that her relation to the defendant was such as to make him responsible for that action. She might have been employed by the plaintiff. Without further showing than that found in the testimony, the defendant would not be liable for the burns or blisters resulting from such hot applications. Judgment for the defendant was affirmed.

ANSWER TO HYPOTHETICAL QUESTION IGNORING EVIDENCE OF X RAY PLATES HELD INSUFFICIENT TO SUPPORT VERDICT

An employee sued his employer for compensation for an injury to his knee caused by striking it against a hard substance. His proof of the relation of the injury to his disability consisted of expert testimony, based on a hypothetical question, that he was suffering from synovitis caused by traumatism. The hypothetical question did not include the conditions disclosed by x ray plates made for the plaintiff one month after the accident. The plates were introduced in evidence by the defendant and showed bone growths in the knee joint of slow formation, resulting from organic processes and not from traumatism. According to testimony not rebutted, the disability was caused by the bone growths. The Kansas Supreme Court held, Kelsey v. Armour & Co., 241 Pac. 453, that the plaintiff's expert testimony was based on a hypothesis which ignored authentic evidence indispensable to a conclusion of value in determining the cause of plaintiff's disability, and was insufficient to sustain a verdict in his favor for permanent disability.

A Few Instances of Nature's Cure of Gallstone Disease and the Occasional Necessity of Surgery to Complete It*

A Plea for Conservative Surgery

MAX EINHORN, M.D.
New York

Not long ago I briefly mentioned a case of gallstone disease (1), in which a diagnosis of the passage of a gallstone direct from the biliary passages into the duodenum, through perforation and previous plastic protective adhesions, could be made with certainty. This particular case resulted in a perfect cure. Similar events occur not infrequently and either pass unnoticed or are recognized later on by complications or in operative procedures on the gallbladder or gastrointestinal tract.

Nature's attempt at a cure need not always be successful. Perforation may occur before the protective adhesions have become sufficiently developed and an outpour of infected bile into the peritoneal cavity may take place. Even when the new communication between the gallbladder or the biliary ducts and the duodenum has been successfully established and one or more big stones have been emptied into the intestine, there are yet three important dangers for the future of the patient. One danger is the occurrence of pancreatitis due to pressure by the newly formed adhesions. Second, when dealing with big stones there is the possibility of ileus, the calculus causing obstruction in the lower parts of the ileum. As is well known, the lumen of the small intestine is usually a trifle smaller the nearer we get to the end of the ileum. The gallstone which has succeeded in passing through the jejunum and the upper ileum finds difficulty in moving on in the second half of the ileum and becomes firmly lodged in the lower portions of this part of the gut. Then we have the typical picture of ileus. There are instances on record in which even in these difficult situations—when everything looked almost desperate—a cure still took place, by the dislodgement of the calculus and its evacuation in the fecal matter. In most instances, however, surgery is called for and is usually successful, if a diagnosis is made in time.

The third danger is the occurrence of scarry contraction or distortion in the neighborhood of the perforated duodenum, which leads to grave disturbances in the emptying power of the stomach. This condition is quite common and usually recognized at laparotomy, seldom before.

In all three sequelæ mentioned surgery plays a vital part for the recovery of the patient.

I shall sketch briefly a few cases illustrating the three main complications.

ILEUS DUE TO BILIARY CALCULUS

CASE I.—June 8, 1924. K. P., female, single, fifty-five years old, had always been well until about two weeks ago, when obstinate constipation, eructations of gas, and occasional vomiting set in. On examination the liver was found considerably enlarged (almost a hand's breadth below the right costal margin) and hardened; at the same time being painful to pressure. The gallbladder could not be mapped out, but there was tenderness in the region where the gallbladder was supposed to lie. Enlarged veins were visible over the abdomen between the navel and the edge of the liver.

The patient was sent by me to the Lenox Hill Hospital, where she was in Dr. J. Kaufman's ward. The examinations of blood and urine revealed the presence of diabetes mellitus. The laboratory findings on June 13, 1924, were as follows:

Blood: red blood cells, 3,500,000; hemoglobin, 75 per cent.; leucocytes, 6,400; polymorphonuclears, 64 per cent.; lymphocytes, 36 per cent.

Blood chemistry: urea nitrogen, 17; uric acid, 2.1; creatinin, 1.7; sugar, 2.80.

Urine: albumin, +; sugar, 1.8 per cent.; casts, +; white blood cells, +.

On June 26, 1924, the x ray showed persistent deformity of first portion of duodenum, possibly due to extensive adhesions, although usually proved to be duodenal ulcer (Dr. Stewart). Stomach contents, HCl=32; T. A.=48; no blood. Patient was kept on a diabetic diet; reached 1600 calories without sugar or insulin. The patient was discharged on July 7th as improved.

On December 7, 1924, she was readmitted to the Lenox Hill Hospital; this time to the surgical division of Dr. H. Fischer.

History: The patient had never felt really strong or well since leaving the hospital six months before

*Read by title before the American Gastroenterological Association at Atlantic City, N. J., on May 3, 1926. From the Lenox Hill Hospital, New York.

Copyright, 1926, by A. R. Elliott Publishing Company.

There were several attacks of abdominal pain, associated with vomiting, lasting several days. She had lost little in weight. For the past two days there had been continuous diffuse cramplike pains in the abdomen. Bowels did not move for two days. The patient vomited more than she took, the vomited matter being yellowish brown in color.

Status præsens (December 7, 1924, Dr. Meynen). Not much changed from previous examination. Dilated abdomen, veins still there, liver edge nine cm. below right costal margin. Tenderness in both lower quadrants.

December 12, 1924: Patient was seen by me at the hospital. The diagnosis was intestinal obstruction due to a malignant disease or to adhesions and operation advised.

December 14, 1924. Pain and vomiting persisted, later presenting fecal odor. No spontaneous bowel movement, although enemata were successful. X ray by Dr. Stewart.

December 15, 1924. Marked obstruction in small intestine, probably near cecum. Entire large intestine dilated; twenty-four hour gastric retention. Urine: albumin, +; sugar, 0; casts, +; white blood cells, 3+; casts, 2+; slight fever, 98.6° to 100.5°.

Operation was performed by Dr. Sauer, December 15, 1924. There was found hypertrophy of muscularis of small intestine with adhesions around gallbladder, to duodenum and to omentum. Gallstone of immense size was found in lower ileum causing obstruction. An enterotomy was done. The patient made an uneventful recovery. The stone (Fig. 1) weighed 15.85 gm.; circumference at widest part, 9 cm.; length, 45 cm.; consisted principally of cholesterin.

The great interest of this case lies in the fact that the large stone filling the gallbladder first caused swelling of the liver and pancreatitis with glycosuria. Then, after rupturing the gallbladder and perforating into the duodenum, there was relief from glycosuria, but later on when the stone moved down the ileum, which is narrower than the jejunum, symptoms of ileus developed and persisted. Enterotomy and removal of the stone brought perfect relief. It was wise of the surgeon to limit his work to the enterotomy and not to interfere with the gallbladder and its adhesions. Had he done more the patient's chances for recovery would have been bad. Conservative surgery saved the patient's life.

CHOLELITHIASIS AND SUBSEQUENT JAUNDICE DUE TO CHRONIC PANCREATITIS

Case II.—September, 1924. A. M., male, seventy-seven years old, complained of loss of appetite and yellow color of the skin for the past two months. He had lost about ten pounds in weight.

Previous history: For the last eighteen years the patient had had numerous attacks of severe upper abdominal pain on the right side, radiating to the back and up the shoulder blade, requiring hypodermic injections of morphine. The attack would last from six to ten hours and be followed by periods of freedom lasting six months to a year. Several of these attacks were accompanied by jaundice. The patient had been seen by me after one of those attacks with jaundice about fifteen years ago in consultation with Charles and Edward Ill. The duodenal contents were examined and the bile found turbid, containing numerous cholesterin crystals and a few pus cells. Inasmuch as the patient refused operative intervention and a sojourn to Carlsbad did him good, we decided to let him take the Muehlbrunnen waters at this resort. Each year, thereupon, this trip was undertaken with apparently good results, until the last period, when the jaundice developed without much pain and remained stationary.

Fig. 1.—Gallstone of K. P. (Case I) removed from the ileum by Dr. Sauer on September 26, 1924.

On September 19, 1924, his skin was icteric; chest organs intact. There was some tenderness over liver and gallbladder region; liver was swollen, extending three fingerbreadths below right costal border. Urine contained biliary pigments; no albumin, no sugar. Gastric contents: HCl +, acid=65. Duodenal bucket string test showed a blood stain corresponding to lesser curvature of stomach and bile discoloration below sixty-three cm. The duodenal contents examined in the fasting state on September 19 and 20, 1924, showed:

September 19, 1924: Dark yellow, turbid, alk.=20; numerous blackish particles, some stony hard (calcium bilirubin crystals), mucus. After five per cent. peptone, 60 c. c., a trace of color reaction, beginning at ten minutes and ending at fourteen minutes (amount 10 c. c.). Total twenty minutes=30 c. c. A=3; S=1; T=2.

September 22, 1924: Dark yellow, brown, very turbid; calcium bilirubin crystals); few cholesterin crystals; mucus. A=5; S=1; T=1. After twenty-five per cent. glucose (60 c. c.) no color reaction. Digestive test capsule recovered after thirty-six hours: potato, fat, thymus and some nuclei present.

The Graham test done with sodiotetraiodo (1.5 gm.) given through the duodenal tube did not give any gallbladder shadow. The diagnosis of gallstone colic having been made long ago, it was thought that there would be a cystic duct occlusion by a stone and partial occlusion of the choledochus either by stone or by a pancreatitis.

An operation was advised and performed by Dr. Edward Ill on September 26, 1924. When the abdomen was opened it was found that there was no gallbladder, the latter having been destroyed and replaced by dense adhesions. The pancreas was found enlarged and its head compressing the choledochus. The originally planned operation of cholecystgastrostomy could not be carried out as there was no gallbladder. A tube was then inserted in the vestige of the former gallbladder and biliary drainage established this way. Patient made a good recovery. The drainage was kept up for quite a while (about two months) and the jaundice had disappeared completely. In this patient the stones must have perforated and destroyed the gallbladder. The dense adhesions may have led to pancreatitis which by compression caused the jaundice. The biliary drainage relieved the ten-

sion and brought relief to the pancreas. The patient has enjoyed good health ever since and is now nearing his seventy-ninth year in good physical condition.

Here, as in Case I, conservative surgery saved the patient's life. Any more extensive interference would have certainly proved fatal.

HYPERCHLORHYDRIA AND CHRONIC CHOLECYSTITIS WITH BEGINNING PYLORIC OBSTRUCTION DUE TO AN ULCER NEAR THE PYLORUS

CASE III.—May 30, 1918. V. F., male, about fifty-six years old, was troubled for four or five years with recurrent attacks of pain two hours after meals, lasting several weeks, with periods of intermission lasting six to eight months. Treatment with alkalies brought relief for some time.

In May, 1919, the patient was again troubled, principally with gastric distress two or three hours after meals, accompanied by heart burn and severe constipation. The examination showed gastric contents: HCl +; Ac.=60. The duodenal bucket string test showed a blood stain about twenty-one inches from the lips, and bile below twenty-three. The duodenal contents examined on June 1st, in the fasting condition, revealed bile turbid containing numerous cholesterin crystals. The diagnosis was ulcer near the pylorus and chronic cholecystitis.

As the patient was suffering a great deal with vomiting, it was decided to operate. Dr. Willy Meyer concurred in the diagnosis and advice. When the abdomen was opened the pylorus was found adherent to the gallbladder, the latter being imbedded in dense adhesions. These were probably caused by the passage of stones and the protective influence of Nature. It was deemed unwise to attempt a cholecystectomy under these conditions. A gastroenterostomy was then done and the gallbladder with its adhesions left alone. The patient made a rapid recovery and has remained well ever since.

REMARKS

In going over the three cases described above we notice that they all presented gallbladder lesions, which Nature tried to remedy by removing calculi through a perforation after forming dense adhesions over gallbladder and duodenum. In these cases later on secondary disturbances developed which required surgical aid. In the first there was a severe ileus; in the second, a chronic pancreatitis with jaundice; and in the third, partial pyloric obstruction due to adhesions. At the laparotomy the question was whether anything should be done with the gallbladder itself, the original seat of the troubles, causing the secondary lesions. It was decided to do only what was absolutely necessary to remove the dangerous complication and leave everything else untouched. It was believed that Nature's protective walls should not be interfered with excepting when absolutely necessary. This policy proved correct, for all three patients became entirely well.

In a number of other instances of a similar type, in which an attempt was made to remove all adhesions and to reestablish more normal conditions along the gallbladder and stomach (doing, for instance, a gallbladder plastic operation and a gastroenterostomy at the same time) there was frequently a fatal issue.

The keynote of this paper, in which I have selected three cases as illustrations of a greater number of similar instances, is: Do only the surgery that is absolutely essential for the life of the patient, and do not bother with anything else, or *do conservative surgery.*

The Ultimate Treatment of a Radical Mastoid Operation

GEORGE B. McAULIFFE, M.D.
New York

Case I.—J. L., aged twenty-two, had a radical mastoid operation done six years ago for an otorrhea which had existed for nineteen years. It had never healed. It was never washed. He had treatment of various sorts—powders and for a time instillations of a few drops of ether daily. His ear was filled with crusts and detritus and he had been told that it would never get better.

The ear was syringed thoroughly, dried and filled with ether. This treatment was carried out twice a day. After a week instead of ether, mercurochrome in fifty per cent alcohol (five per cent solution) was instilled after syringing. The cavity now began to look better. Dried casts of various parts were taken away. At present he is syringing with boric acid twice a day followed by instillations of five per cent mercurochrome and insufflation of boric acid powder to act as a sponge for residual moisture. Raw granulations have been touched up with twenty per cent nitrate of silver. He has been seen once or twice a week for two months. At present the cavity presents a shiny epidermis in all situations except a small spot below. The ear gives him no concern now although he has absolute conduction deafness.

Case II.—Mrs. P., aged thirty-seven, had had otorrhea off and on since she was fourteen years old. After her first child was born the right ear ran for a long while. After the birth of her second child it began again. She had some mastoid pain and dizziness. A radical operation was done five years ago. The discharge did not cease. It was treated constantly. The same injunctions about moisture had been given. She became quite despondent. I saw her three weeks ago and instituted the same line of treatment detailed above in Case I. There was nothing remarkable about the measures I advised except thorough cleansing and sterilization and absorption of residual moisture. At present her ear gives her no trouble. She has two spots which are not covered and some granulation tissue behind and in front of

the fragment of posterior wall. I look forward to a good result. I may be too sanguine but at least she feels better than she has in five years.

Case III.—Mrs. B., seen in November, 1924. The right ear began discharging sixteen years ago and was treated. In November, 1903, a radical mastoid was done. After operation there had been no discharge and hearing was good. No skin grafts had been employed. In February, 1904, she had fainting spells, dizziness and a swollen face. Another operation was done. In April a third operation was performed. The ear was then apparently healed. Six weeks ago, she began to feel as if the ear was packed. She had tinnitus and the hearing began to fail. The left ear began discharging twelve years ago. On September 1, 1903, the radical mastoid operation was done. The ear did not heal. Shortly afterwards a second operation was done. Six weeks ago the same feeling of a packing with tinnitus came on. Both ears healed with a tight skin. The hearing in the left was now better than in the right. The left ear had been grafted.

In 1910 the hearing was poor—about equal in both ears. The acoumeter was heard about two inches. The right ear was moist. Tinnitus annoyed her.

In 1917, when her head was low she became dizzy. The dizziness lasted for some time. When last seen she was troubled with tinnitus and vertigo when in bed. It was increasing in intensity. Both ears were healed. Her hearing was poor, and the tinnitus and vertigo were increasing. I followed this case for thirteen years and while the operative work was successful after three attempts on the right side with no grafting and two procedures on the left with grafts from the thigh, the end results of function were distressing.

I cite these few cases as examples of many radical mastoid operations which have come under my observation. They naturally awakened the inquiry, "Why are these patients not entirely free from aural disturbance after having undergone an operation not only severe but apparently useless, except in the particular that they are free from the danger of intracranial complications?" If the patient was aware of the facts that in many instances no cure of the discharge would be guaranteed; that hearing would not be conserved; that even if after the ears had apparently healed relapses were apt to occur, would they readily assent to such an operation except in these instances where an immediate operation was necessary to prevent intracranial sequelæ? How many of the radical mastoids fall under the last caption? Very few. There is no doubt that there are fewer "radicals" done at present than a decade ago. Proper treatment of the aural discharge, improved methods of conservative medication, the widespread propaganda of the danger of infected ears, all have contributed to the prevention of conditions that are within the danger zone.

I am reminded of the observations of Dr. E. J. Gill, in the *Southern Medical Journal,* who states that "inexperienced aurists who are not indifferent to the delicate anatomy of the ear do the operation; that cases are not carefully selected; that useful hearing is often destroyed and that the postoperative care is neglected." Aurists would rather operate than treat. A certain number of ears must be operated on radically to round out their experience or quiet their *furor operativus.* J. Foster in the same journal states that thousands of radical mastoid operations are done which could have been cured by conservative treatment and adds that not so many are done now." He states also that "recurrence comes from infection from the Eustachian tube or from rapid exfoliation of new and poorly nourished epithelium, and patients should be seen from time to time for two or three years." How many get this postoperative advice. Very few, judging from cases that are seen.

Andrews, in commenting on these statements, states that the poor results are due to insufficient flaps and too small a meatal opening and he also advises that patients should not be dismissed until shiny epithelium shows; that moisture should be avoided. I feel that the last injunction is misinterpreted. In endeavoring to avoid moisture cleanliness is interdicted. So we find, especially in children and in many adults, ears filled with dirt, wax and pus all interacting on one another. It seems almost an argument against focal infection to see the apparent tolerance of masses of septic detritus lying in contact with a raw surface in what is practically a pocket. What a commentary on aural surgery! Does the fault lie with the patient or with the aurist? Surely not in the majority of cases with the patient, because he is ignorant. If he is not stolid he seeks relief from the condition and passes from one to another aurist often without relief. Many are told that their condition can not be cured. They are instructed not to syringe their ears because moisture is bad for them. So they accept the condition—perhaps worse than the original one—with a resignation truly remarkable.

My contention is not that the radical mastoid operation is unnecessary but that in many instances it can be avoided. The patient should have a square deal. If the operation is done for the purpose of preventing intracranial sequelæ it is absolutely the only surgical method of accomplishing it. But the patient should be informed that the treatment does not cease a month after the operation; that it may be necessary to look after the ear for years. If the operation is done for the cure of a chronic otorrhea no promise should be held out for a permanent cure. No promise should be made that the hearing will improve. The operation will give him practically a dead ear in the majority of cases. Furthermore, that the surgeon should feel the necessity of a rigid follow-up procedure until the patient is as well as the operator can make him. He should not throw the case after doing the operation into the scrap heap of experience.

There is still too much *ipse dixit* in medicine and Aristotelian obedience does not make progress. Ears that are foul should be cleansed. If squamous epithelium cannot stand this it is surely not worth much as protection. I believe that the recurrences of the discharge are due to sepsis more than mere moisture. Therefore mild antisepsis with due regard to the integrity of the epithelium covering will preserve rather than destroy the epithelium. Drying the cavity can be easily done and the old practice of boric acid insufflations, provided the patient or the ear shows no intolerance to the drug, will care for the residual moisture and serve to exclude possible external aerial infections. It is a difficult matter to convert a mucous cavity into an invaginated skin cavity.

It may seem that the views stated above are very pessimistic, but I am only stating what I see. It is a distinct surprise to me to see a perfect radical mastoid operation. I know there are many. If the operation fulfilled the indications, there would not be so many modified radical operations advocated. This acknowledges the weak points of the procedure. We have yet to see a better mode of attacking the disease—one that will not practically destroy the end organ of audition: one that will give a better cosmetic effect: one that will not leave the patient with an open cavity subject to every external insult. The principle of the operation is correct. The method is open to many objections some of which I have alluded to perhaps too strongly but my opinions are only the result of my observations on the old radicals of which nothing is ever heard. Therefore, the ultimate treatment should interest those who lightly decide on this procedure for the cure of a chronic discharge which may never eventuate in intracranial complications.

26 West Eighty-seventh Street.

The Chemical Aspects of Life and Disease*

ELLICE McDONALD, M.D.

Philadelphia

It is with some diffidence that I come to speak before this society of accomplished chemists, because I have a full realization of my shortcomings as a chemist. I have had to learn my chemistry in the last few years, and the job is still far from being well done. However, my excuse is my keen desire to gain the help of chemists in our study and turn the minds of chemists toward the colloid problem of life and the modification of normal life into the deviation of disease. Life is the continuance of colloidal reactions in an aqueous medium and research into these vital processes is essentially a chemical colloid problem. In learning to think of life in terms of colloid cell changes, I have come to think of vital problems and their deviation in disease in a language but poorly understood by my fellow doctors and yet I am not sufficiently informed to discuss these chemical problems on a full basis of equality with chemists, so that I am like the coffin of Mohamet, suspended between the earth of medicine and the heaven of chemistry, hoping that some day I shall be translated to that paradise where I can understand the application of the De-Bye-Hückel equation to the processes of the protoplasmic cell.

It is peculiarly appropriate that I should appear before you, incomplete though my contributions may be, because it was the chairman of your programme committee, Dr. J. B. Hill, to whom I turned for chemical help several years ago and whose direction as to the literature and workers was the beginning of our study into the colloid forces of life. And this is my way of giving thanks to him and to you. I shall speak frequently of our investigations into life and disease, and, when I use the editorial "we," you will please understand that I do not mean myself alone, but this must include my collaborators, chief of whom are Dr. S. D. Ludlum, Professor of Psychiatry; Dr. Elton Mayo, Rockefeller Fellow in Psychopathology; Dr. Josephine Gleason, Assistant Professor of Psychology in Vassar College; Dr. W. G. Karr, Assistant Professor of Biochemistry; Dr. Andrew Godfrey, Surgeon to the Chestnut Hill Hospital; Dr. W. Seifriz, Assistant Professor of Botany; Dr. Crowder of the Department of Clinical Pathology; Drs. Reinhold, Blodgett and Saylor, chemists, as well as others. In addition we have had help and assistance from True, the botanist; Langmuir, the chemist; Ralph Lillie, the biologist; Mansfield Clark, the chemist; Clowes, the biochemist; Donnan, the colloid chemist; Stockard, the embryologist, and many others to whom I once more take this opportunity for giving thanks.

Our study is incomplete; this is the beginning, not the end of experiment, but I welcome this opportunity to bring it before you because we want your help and to have your minds preoccupied with this problem so that the knowledge of life may be advanced. So many abstruse chemical problems arise upon which we need advice and assistance, and we find it is easier to inform a chemist into the biological processes than it is to instruct a medical man in colloidal chemistry. The medical man has been interested in end results, and there has been no thread of reason running through the study of medicine as the atomic theory does through chemistry. The medical man thinks in terms of the pneumococcus and the consolidation of lobar pneumonia, without considering the intervening processes. It is as if chemists knew nothing of the atomic theory and considered the reaction of oil of vitriol with copperas as to form new end results. The late Sir James Mackenzie, the heart specialist, who left the largest and most lucrative consultation practice in London to study life and disease in the obscure little town of St. Andrews, and there founded and supported an institute, said in the last letter he ever wrote, "For years I had been gradually becoming convinced that the whole tendency of medical research was on wrong lines; it was devoid of fundamental principles, was haphazard and could not supply the kind of knowledge which would enable us to solve medical problems . . . I saw that there was undoubtedly a great fundamental principle, which, if discovered, would do for medicine what the atomic theory has done for chemistry." This letter was published after Mackenzie's death and he was unable to complete his research. It is for this fundamental principle that we search, and it must consist in the application of the atomic theory to vital processes and it is for this that we bring our unfinished work before you and ask your help as chemists. And in relating this study, you will realize that many things must be stated broadly and

*Address before the American Chemical Society, April 15, 1926.

generally, and so make allowances for certain lack of detail in statement due to the shortness of the time and the necessity to review all the processes of life in one hour.

The most interesting thing in the world is the contemplation of life. The human animal is busy about his own affairs and interested in his own organization and its relation to the world. So, in regard to the study of life, it is with the human system or organization that our chief interest resides. Man, being a vertebrate, has most of the mechanism of his body organization in common with other vertebrates; but a part of this mechanism is more highly developed in him and this particularly applies to the specialized character of his two nervous systems, but this is a difference only in degree. Jacques Loeb has defined organisms as chemical machines, consisting of colloid material capable of growing and automatically reproducing themselves.

The application of this definition to the human animal shows that it is correct within limits, but falls short of many functions and activities of man in the varied phases of his life's career. Growth and reproduction are but two of his activities and the definition must be elaborated to include nervous action and control (voluntary and involuntary) maintenance and indeed decay or age.

There are four principles in the study of man's life which are fundamental and which have not been much considered: *1, the application of the energy of life from atoms; 2, the colloidal structure of protoplasm or body stuff; 3, the control exercised over the relation and processes of the first two factors by a special group of cells, mainly localized in the involuntary nervous system and 4, the effect upon his body processes of man's particular and peculiar psychic power of mentality and emotion which he has more highly developed than the other vertebrates.* To attempt to explain the process of man's life, these four factors (at least) must be considered and they are so interlocking and mutually influencing that, unless they are considered, any research in man's life, whether of the proper mechanism (health) or its deviation (disease and age) will be without fundamental principles.

The processes of life have to do with the living: death is inarticulate and unresponsive. The real concern of man is with life and the processes of life; his physical and mental activity are associated with the movement of living matter as distinguished from nonliving matter. Living matter exists in definite ordered arrangements or schemes and not in a diffuse, unorganized or formless state. Characteristic of the association of life is the ordered or planned arrangement carried out to the most minute detail and this plan or order is absent in nonliving protoplasm—there the scheme is not complete, systematized nor arranged.

But in living organs, certain cells frequently control other cells as to their activity and energy functions. The cell is never at rest, always discharging or renewing energy, never grows old so long as the blood supply is good, never gets tired while its nutrition is supplied. Every living cell is a practical organic and physical chemist, conducting analytic and synthetic processes of the most complicated order. But its activities are dependent upon other cells. In certain cells the power of control is more highly developed, as in the nervous system whose function is the control of protoplasmic energy from a distance.

Life is the result of the reaction of energy and protoplasm, and protoplasm is an apparatus for transforming energy. These processes are dependent upon chemical activity, but they are not governed by the rules of a simple chemical system. In vital activities, the processes are based upon colloid structure, and mechanism is therefore as important as chemical reaction. Protoplasm which is the basis of life is a colloid and the unit of protoplasm is the cell.

Protoplasm, although it consists largely of substances which are soluble or suspended in water, nevertheless maintains itself within the body in a watery medium. This is due to the fact that protoplasm exists mainly in units, called cells; and the protoplasmic cell is not miscible with water on account of its differentiated outer layer or cell wall and is maintained intact so long as the cell boundary protects its integrity. This membrane is semipermeable (only certain selected substances can pass through) and protects the interior from dissolution and disintegration by the water. So that this house of our body is made up of cells as bricks, but these bricks have each a protecting film which allow certain things to pass in and out and maintains the bricks intact. The durability and continuance of this film depends, not only upon the environing medium (the water part of our bodies), but also upon the specific constitution of the protoplasm, so that the cells of different quality or kind of protoplasm have cell boundaries of a different character.

The degree of chemical complexity in material on earth is definitely fixed by temperature. Project your minds backward to the high temperatures of the beginning of the formation of this earth when only such forms of matter as we term elements could remain in equilibrium, and probably many of them were decomposing as radium is today. At a somewhat lower temperature, binary compounds such as oxides could remain in stable equilibrium. Still lower in the temperature scale, saline compounds of the halogens and of neutralized acidic and basic oxides can stand the heat and finally the carbonates of the alkaline earths in a labile equilibrium according to pressures of carbon dioxide. But it is only at a much lower temperature that compounds complicated in structure can exist in equilibrium and, for compounds necessary to life, the temperature range is very limited. As soon as the temperature will admit of carbonate formation, the carbonates come into existence. When equilibrium conditions admit of it, matter of its own properties tends where energy is available to take on complex forms with cooling. Next in order of evolution were the inorganic colloids. The unit now passes from the atom to the molecule and complexes of molecules form colloids with alteration in temperature, and instead of single atoms forming single, simple molecules, molecules behave as atoms and units with a new order of affiliation to form colloid molecules. With increasing complexity of structure, the equilibrium of the colloidal aggregates approximate more and more to the labile, easily destroyed and readily reconstructive arrangement characteristic of life. This is the transition of

the inorganic colloid to the living colloid of the cell structure. The discovery that inorganic colloids are capable of absorbing external energy forms and so building up complexity, will yield a new outlook on life and bridge the gap between the inorganic and organic, between the nonvital and vital forms of matter.

Graham, the father of colloid chemistry, spoke of colloids as a dynamic form of matter and of crystalloids as a static form. But now chemistry is being translated in terms of free energy and the gap between the salt and cell is being markedly lessened. So we find living organisms exist as a number of exceedingly complicated colloid structures, the origin of which can be traced directly or indirectly to the energy of sunshine and fashioned into chemical energy in organic colloid bodies of which the unit is the cell. In addition, life has a very limited range of p.H. The plasma of the human blood can not vary more than from p.H. 7. to p.H. 7.9. At the higher p.H. the tendency is for the bicarbonates to turn to carbonates from the use of carbon dioxide utilizable for carbon fixation. In synthesis, there is a tendency toward alkalinity and the change from bicarbonates through carbonates to hydrates of the chief cations.

In living organisms, the cell is the simplest unit capable of continuous life. In the human being, it is a complete and autonomous unit, capable of vital reactions and changes and, by these, influences profoundly the chemical activity of the cellularly organized body. In typical living cells, the external protoplasmic layer has all the properties of a semipermeable membrane which is impermeable, or permeable with difficulty to the water soluble substances of low molecular weight, present in the protoplasm or its surroundings, but it is freely permeable to water. The protoplasmic cell can thus preserve a chemical composition different from that of the surroundings without interference which would result from a free or unrestricted diffusion or interchange. The chemical composition and crystalloidal content of the cell are widely different from that of the surrounding medium.

In the human body, the aqueous medium (the watery blood and tissue juices) has much more sodium than has the interior of the cell within the cell boundary. The other salts of potassium, calcium and magnesium (which with sodium make up the important salts of the body) are in different proportion within and without the cell (in the cell interior and in the plasma of the blood). The salts of the blood plasma are the salts of the ocean, but not the salts of our present ocean which is considerably more alkaline. The plasma salts are in the proportion of the salts of a primeval ocean, and this has suggested to A. B. Macallum that the circulatory fluid of man is a reproduction of proportions of the Archean Ocean of late pre-Cambrian or early Cambrian times. The cell is older than the blood plasma because it first existed at large in the primeval sea as a single particle in salty water and unenclosed. The cell became a closed system earlier than the closure of the blood system and finally became surrounded by an envelope (as in the circulatory system) taking with it the composition of the sea water of that time; the cell migrated, so to speak, from the primeval ocean and carried with it its own small sea, confined within boundaries, so that it continues to have the aqueous medium it requires.

Geologically speaking, the cell is, therefore, older in evolution than the blood plasma in which it exists. The cell is pre-Cambrian and the blood is late pre-Cambrian, or early Cambrian. So for these billion years, the cell and its liquid phase (the blood plasma) have been existing with different salt content, the salts in the interior constantly striving to get out and the salts of the exterior constantly trying to get in; in their struggle the ions produce electron interchange and potential differences across the cell boundary. Their heredity is the sum of the environmental processes. The colloids are amphoteric (neutral or without potential) but the addition of crystalloids by producing the attraction of ions to the surface or away from the surfaces produce potential differences. It is for this reason, that the salts of the body, although amounting to less than two per cent. of the body weight, are of such supreme importance. Colloids have to be vitalized by crystalloids before they become potentially active. The human vitality depends upon the stimulation of the colloids by inorganic salts for the continuation of life processes and alteration in these salts, within and without the cell, produces alteration in protoplasmic action which is dependent upon the resultant change in the structure of the colloid with alteration in structure, osmosis, surface tension, viscosity and potential difference. It may be taken as an axiom that a constant bioelectric variation is associated with every constant life or physiological process, and the change in bioelectric variation depends upon potential difference change from the inorganic salts.

The protoplasmic cell is relatively acid in relation to the blood plasma or serum. The cell is usually upon the acid side of neutrality and the blood plasma is considerably upon the alkaline side. There is then an acid or less alkaline colloid cell, surrounded by a more alkaline aqueous colloid medium (the blood) with a cell membrane or boundary interposed. An ideal arrangement is thus made for the production of potential differences (electrical inequality) and membrane equilibrium. The bioelectric variation thus is capable of easy and facile changes and electron transfer produces such vital processes as oxidation-reduction, peptization, coagulation and all the varied processes of life. The action of the forces then can be crudely represented in the following scheme:

nucleus, electron	cation, anion	electrolyte, water	protoplasmic action or vital processes.
nucleus, electron	colloid, film	cell boundary	protoplasmic action or vital processes.

The human system is thus a heterogeneous system, but so perfect as to act as an almost homogeneous one. It may be considered as a negatively charged suspensoid, where the particles are negative in regard to the liquid phase and their stability may be changed by alterations in charge. The human cell acts as an electrode reversible to cations.

Cations are more effective against the cell boundary as the positive cations are attracted to the negative cell surface. However, Murkerjee, of Calcutta, has shown in negatively charged suspensoids that the cations divide themselves into two classes, the uni-

valent cations which increase the stability and the bivalent and trivalent cations which decrease the stability of the negatively charged suspensoids. The univalent cation has a single electrical charge or electron to give and the bivalent and trivalent cations have two and three electrons to give. Substances like sodium and potassium are univalent and calcium and magnesium are bivalent and these have different action, so that there are sodium and potassium different in action in the human body from calcium and magnesium and these are the four important inorganic elements of the blood and of the body.

In the human system the univalent sodium and potassium salts produce alkalinity and the bivalent calcium and potassium salts produce acidity in the secretions and in the liquid phase (the blood plasma). Injected in the cell, sodium and potassium salts produce liquefaction or dispersion and calcium and magnesium salts produce coagulation or aggregation of the colloid. There is a different action, therefore, of the univalent and bivalent cations in the human body and the same holds true for the effect upon nerve action.

The nervous control of the functioning cells of the body is exercised mainly through the vegetative nervous system. There are two nervous systems in our bodies: one the cerebrospinal or voluntary, with which we think and cause our voluntary muscles to move, and the other, the vegetative (also called sympathetic, involuntary or autonomic) which presides over our unconscious life and the action of our great organs in circulation, digestion, various secretions and metabolism. This vegetative system controls the unconscious functions of the body, the heart that beats, the lungs that breathe, the intestines that digest, the kidneys that secrete, bloodvessel capillary amplitude, metabolism and all the varied mechanism of life outside of voluntary controlb. This nervous system is called vegetative because it manages the part of us that is like a vegetable, while the cerebrospinal nervous system (the brain and its ramifications) takes care of all of us that is unlike a vegetable—the thinking, moving part. It is estimated that the control of the will over the voluntary muscles through the cerebrospinal system cannot possibly expend more than twenty-five per cent. of the energy of the body, while the organ functions, controlled by the vegetative nervous system, constantly expends daily at least seventy-five per cent. of all the energy in processes of which we are unconscious. It runs the show, and leaves the cerebrospinal system free for thought and action.

These two nervous systems are independent and interdependent in the reciprocal relation so frequent in the human system. There is a connection between them in the brain and spinal cord and our well-being is dependent upon harmonious interaction. The voluntary actions relate the creature to its surroundings, but presume or are directly dependent upon harmonious cooperation of the involuntary activities. The development of the central nervous system has been of immense importance in the evolution of man. The steady growth and complexity of the central nervous system has made possible the development of *will power* with all that it implies and the domination of man over the rest of the animal kingdom. Since this has been the progress of evolution, the more this concentrated cerebral (voluntary) system is freed from the subordinate (involuntary or vegetative) system with the continuance of harmonious interaction, the greater will be the advantage to the animal. The cells of the vegetative system originally formed part of the central or cerebral system and, by their migration toward the great organs, freed the central nervous system from a large mass of nervous effort and so enabled the brain to exercise general control over the whole scheme. It is as if the central nervous system found it had too big a job and delegated the routine to another, the vegetative nervous system, while it remained to direct the destinies. The cerebrospinal system is the captain who cons the ship, while the vegetative system is the multitude of engineers, firemen, coal passers, cooks, stewards, etc., that keep the fires up, the engines running and feed the crew and passengers.

But there must be pleasant relations between the deck gang and the black gang, between the bridge and the engine room, otherwise the voyage will be a hard one. The central nervous system can affect and is affected by the condition of the vegetative system. The vegetative system must do its work well to leave the brain free to control and still be so close, as to allow the brain to react to changes and needs of the body system. Yet if the relation is too close, such things as emotions will be too readily felt and make too great impression on the action of the human system (in digestion, circulation, etc.), and so cause upset in vital equilibrium.

So that we have found in human life three most important factors in the production and control of its processes: 1, the application of energy of life from atoms; 2, the colloidal structure of the human protoplasm, and 3, the control exercised by the vegetative nervous system over these processes. These are the three great fundamental principles of life in the vertebrate and a study of their action and deviation is necessary to the understanding of human vital processes.

The control of the vegetative nervous system is largely in its action upon involuntary muscle, of which example is in the pupil of the eye, the heart, the muscles of our blood vessels (arteries, veins and capillaries). There are two kinds of muscles, voluntary and involuntary: the cerebrospinal system controls the voluntary and the vegetative the involuntary. The latter is widely distributed in the human body, so that its control is most important. The capillaries of the circulatory system, where most of the interchange of substances with the blood goes on, have smooth muscles (called Houget cells) and, when it is considered that the capillaries in a small man have been estimated by Krogh at a total length of sixty-two thousand miles, or two and a half times around the world, and their total area at one hundred and twenty thousand square yards, the influence of the vegetative nervous system in contracting and dilating these and its effect upon metabolism (or body processes), through this means alone, may be well appreciated. Its control over the heart which normally pumps seven and one half tons of blood a day, equivalent to lifting a ton of blood 122 feet high, is another example of its action. If it makes the heart run too fast and too hard, the work is increased and increase of twenty per cent. blood pres-

sure means using up so much more energy and lifting a ton of blood 152 feet instead of 122 feet high daily. This involuntary system exercises its control in dozens of other ways so that it is vital for vital processes that the engineers and the black gang keep well on the job.

The vegetative nervous system consists of two divisions—the vagus and sympathetic parts. These two divisions are antagonistic and a balance. When one is increased, the other is depressed. The proper tone of vital processes and the involuntary muscle depends upon the even balance of these two parts. In addition, these work in different ways, the vagus division stimulates the stomach and intestine and slows and weakens (inhibits) the heart, while the sympathetic division increases the heart's action (stimulates) and slows up the stomach and intestines. It is as if the black gang on the ship were in two shifts and had care of two engines. The starboard watch of the black gang (the vagus division) makes the cook's galley and the commissariat (the gastrointestinal tract) work hard, but cuts down steam on the turbines (the heart) and the port watch (the sympathetic division) keeps up steam on the turbines, but cuts down on the cook's galley. But both are necessary to proper running, and if one works more than another, it will go hard with the ship. The proper balance of both sides of the vegetative nervous system is then necessary to the proper balance of the human craft.

It is possible in a number of ways to arrive at an opinion of this balance by various examinations of the human body. These are more or less exact and the most satisfactory method is by considering the amount of contraction or dilatation of the involuntary muscles which are contracted by the vagus division in the pupil and gastrointestinal tract and dilated by the sympathetic division of the involuntary nervous system. According to the researches of Ludlum and myself, it is possible by means of x ray pictures of the condition (postural tone) of the stomach and intestines to obtain an idea of the relative vagus-sympathetic balance and find out which of the starboard or port watches of the black gang were working too hard, and which were soldiering on the job, or whether the action was harmonious and in balance.

(*To be continued*)

An Outline of Public Health Administration in Toronto*

CHARLES J. HASTINGS, M.D., C.M., LL.D., D.S.C.

Toronto, Canada

Over three quarters of a century ago Benjamin Disraeli, talking over the heads of his colleagues in the British House of Commons, said: "Public health is the foundation upon which rests the happiness of the people and the strength of the nation, that is why I claim that the first duty of a statesman is the care of the public health."

Surely the mills of the gods grind slowly. In 1918 Mr. David Lloyd George, after having read the reports of the medical examining boards, in an address at Manchester on public health said: "If our nation had been looking after the health of our people as it should have done for the past twenty-five years, we would have had a million more men to put in the field and the war would have been won months before it was."

Every nation in time of war expects every man to do his duty, but whether or not he will be able to do so depends in a large measure on whether or not that nation has done its duty in making possible the development and maintenance of the best physical state of which he is capable. The war that we have just passed through has fully demonstrated to all nations that man power, brain and brawn, is the most valuable asset it possesses. Obviously, then, the first duty of a statesman or of a nation should be the care of that most valuable asset.

It is a comparatively few years since the principal duties of a department of health were considered to be the abating of nuisances, the efficient disposal of sewage and of garbage. However, after the discovery of the germ origin of disease, as revealed by the immortal Pasteur, it then became the duty of public health administrators to discover the haunts and habits of these disease producing germs and the various ways in which they were transmitted from one person to another, and endeavor to protect the public by placing beacon lights on the various rocks and shoals. While every department of public health requires a well organized division of quarantine, in addition to a full knowledge of the possibilities of the transmission of disease producing germs, it was thought for years that these organisms were for the most part transmitted through the air. That has long since been disproved. We know now that the great danger of the transmission of disease is through personal contact, either directly or indirectly. By direct contact is meant personal contact with the individual suffering from the disease; by indirect, the transmission of disease germs from the clinical case through various media. Of these we find that food and eating and drinking utensils are probably the most frequent channels through which they are transmitted; hence the necessity for rigid precautionary measures as regards the safeguarding of our foods from dust, dirt, and fly contamination and the efficient sterilizing of all eating and drinking utensils before being used. The Department of Health in Toronto requires the safeguarding of food from dust, dirt and insect contamination, more especially foods that are not submitted to a temperature that will destroy these germs before being consumed by man. In our regulations for hotels, restaurants and all eating houses, we require a permit, and before

*An address delivered at the Institute of Hygiene, London, England, June 29, 1926.

granting this permit the premises must comply with the requirements of the department, which includes the proper facilities for washing and sterilizing all eating and drinking utensils. These places are inspected regularly and in the event of failure on the part of the responsible parties efficiently to carry out these regulations, they are given timely warning and in the event of a recurrence of this negligence, their license is cancelled.

WATER AND MILK CONTROL.

Control of water supply.—The control of a water and milk supply of any municipality in our judgment is primarily and essentially a government responsibility. The control of the water supply is much more simple than that of the milk supply, inasmuch as it does not interfere with vested rights, the methods adapted being practically uniform in all nations and all municipalities, that is, filtration and light chlorination. In Toronto we make several bacteriological counts of our water every day as taken from the tap which means the water as consumed by the citizens. This is found to be for the most part practically sterile, the colon bacillus not being found present more than once or twice in twelve months. Consequently, our typhoid mortality has become practically a negligible quantity.

Control of milk supply.—The efficient control of a municipal milk supply is a much more formidable problem. In 1911 the Provincial Government passed a bill authorizing all municipalities in the Province of Ontario to frame by-laws and regulations governing their milk supply. Within six months from the passing of this bill, we had our by-laws and regulations in force for the securing of a clean milk supply.

This consisted of the careful inspection of all dairy farms by veterinary inspectors who examine the herds to see that they are in a healthy condition and also the various cow stables or byers from the viewpoint of cleanliness and proper ventilation. Rigid instructions are posted up in all dairy farms regarding the degree of cleanliness essential and the precautionary measures to be taken in connection with the milking of the cows. The hair is required to be clipped short from the flanks of the cow and from the udders so that it may not afford a lodging place for gross material of any kind. No wet milking is permitted and the milkers are required to wash their hands carefully before milking. The milk is immediately removed from the byers or stables to an adjoining milk house where it is strained and chilled as soon as possible. The milk is strained into sterilized cans which have been sealed when sent out and again sealed when returned to the distributor or to the milk stations. It is carefully supervised at every step from the producer to the dairy. The dairy or distributor is required to be equipped with pasturizing plants. This we consider absolutely essential, inasmuch as clean milk, free from gross contamination as determined by the sedimentation test, even though it has been taken from tuberculin tested herds, is not, in our judgment, a safe milk, inasmuch as it may have been handled and thus contaminated by someone suffering from a communicable disease or a carrier of these communicable diseases.

Unfortunately, in this country, as far as I have been able to observe, the great source of danger of cow's milk to the human is bovine tuberculosis. While not wishing to minimize for a moment the danger of bovine tuberculosis, which was demonstrated by all the Royal Commissions appointed in 1901, and by those engaged in research work ever since, to constitute from twenty-five per cent. to twenty-six per cent. of all cases of tuberculosis in infants or children under sixteen years of age, yet there is a much greater element of danger in connection with milk, as has been demonstrated by the fact that in the United States and Canada there have been between three and four hundred outbreaks of the various communicable diseases that have been traced directly to the milk supply, these outbreaks representing several thousands of cases. Obviously, then, the only way to make a milk supply absolutely safe for human consumption is to secure a clean milk and then make it bacteriologically clean by scientific pasteurization which efficiently destroys all disease producing germs. By scientific pasteurization we mean the raising of the milk to a temperature of 145° F. and maintaining it at that temperature for thirty minutes. The milk is then promptly chilled and bottled, the bottles being capped by machinery. The temperature of the milk is not permitted to go above 50° F. until delivered to the consumer.

There was, however, one weak spot in connection with our pasteurization, and that was that we found occasionally that some unscrupulous distributor would run the milk up to a temperature of probably 175°, or even higher, but for a short time. This was done for the purpose of economizing on fuel. Inasmuch as no system of inspection could overcome this, we purchased a sufficient number of Cambridge self-recording thermometers and had them placed on every pasteurizing plant in the city. These thermometers are owned and controlled by the Department of Public Health. Our inspector carries the key and removes the disc once a week. This has made this phase of the work practically fool proof.

Since 1914, when our ordinance requiring all milk not coming up to the standard of certified milk to be pasteurized scientifically and delivered to the consumer in sealed bottles, not a quart of milk has been sold in our city that has not complied with these requirements. In this way we feel that we have efficiently safeguarded our milk supply which is obviously subjected to greater possibilities of contamination than is any other food, and when one realizes that milk is the most valuable food we possess, these precautionary measures are not only fully warranted but absolutely essential. In fact milk is the only perfect food we have. It contains all the elements essential for the development of the infant and young child and is absolutely essential for the developing boy and girl, inasmuch as when it is added to the other food they take in their daily routine it secures for them a properly balanced diet containing as it does all three of the vitamines and the necessary amount of calcium and phosphorus salts that are so essential for bone development and that play a more important role in the efficient development of the teeth than any other food available.

The arguments that have been raised against pasteurization are absolutely untenable, with possibly the single exception of the influence of heat on the vitamines and this applies only to vitamine C, inasmuch

as vitamines A and B have a much greater resistance to the influence of heat and would require a much higher temperature than that necessary for pasteurization to have any deleterious effect. We are willing to grant, however, that a temperature of 145° maintained for thirty minutes may possibly reduce fifty per cent. the potency of vitamine C. However, this is not worthy of consideration in view of the fact that every pediatrist or authority on disease of children, recommends as a part of the routine diet of every infant and child from a teaspoonful to a tablespoonful of orange juice every day, depending on the age of the child. This secures for them an ample supply of vitamine C.

In the light of the knowledge we now possess, even if it were possible completely to control communicable diseases, that would only constitute, as it does, a fractional part of the activities of a department of public health, the aims and objects of which should be the development of a fitter race. In order to do this, we must begin our activities as soon after conception takes place as possible, having in mind, as Galton so fittingly expressed it, "where nature ends nurture must begin." Therefore, as the developing offspring is dependent entirely on the mother's blood for its nutrition, the necessity for efficient antenatal care is perfectly obvious. If the mother's blood is to be kept in a normal condition this means an ample supply of well chosen food that will constitute a perfectly balanced diet, proper hygienic surroundings, efficient exercise in the open air, sleeping in a well ventilated room, and in fact all other matters of personal hygiene essential for physical fitness. Therefore, the first activity of a department of health must be antenatal care, the second, the care of the newborn infant.

This care is provided for the most part by our well baby or child hygiene clinics where the mothers are required to bring their infants regularly for general observations, weighing and measuring, in order to determine whether their weekly or monthly gain in weight is sufficient. The mother also receives advice from an expert on the care and feeding of infants.

The next link in the chain of activities is that of the care of the child in the preschool age. This can best be linked up with the well baby clinics, as by doing so it saves additional organization and minimizes duplication.

The next link after that is the complete physical examination of the child on entering school, every child receiving a complete physical examination during the first year in school. This is always done where possible in the presence of one or both parents. All clothing is removed by the nurse in attendance before the physician begins his examination. If any physical defects are discovered a note is sent to the parents explaining this with a request that they consult their physician. If they cannot afford to have a physician, they are referred to the hospital clinics, that is, the hospital for children. Our nurses follow up these cases and see that these conditions are corrected. We then have medical, dental and nursing service during the entire school period, and another complete physical examination before leaving school. This serves a double purpose. In addition to ascertaining whether there are any physical weaknesses or any organic trouble, it also serves as a vocational guide. Then we have a division of industrial hygiene. By this division all industries in the city are carefully supervised in order to secure for the employees proper heating and ventilation and also, the installation of efficient devices for the control of trade dust.

EDUCATION

This is the most important factor in efficient public health administration. Education constitutes nine tenths, if not ninety-nine hundredths, of the permanent efficiency of public health administration. We are fortunately living in an age where people no longer want to be treated as machines. They want to know why they are required to do certain things and when they obtain this knowledge they are usually ready to do them and in this way, in the vast majority of cases, we can secure their full cooperation. However, education is not as simple as it might seem. Carlyle said many years ago that only one person out of five thousand thinks. I am of the opinion that if Carlyle had had the experience that most modern administrators of public health have, he would have said that only one person out of fifty thousand thinks. The human brain is lazy and likes to go along the line of least resistance. Therefore a part of our duty in education is to train the mind and make it more receptive. This can best be accomplished by our exercising patience and not being afraid to repeat. The experience of all teachers and educators has been that the secret of education is, as Sir William Osler expressed it, "reiteration, reiteration, reiteration," and to accomplish this one requires to express oneself in just a little different language so as not to produce irritation and at the same time make sure that a nonerasible impression has been made on the minds of our people. The process of education in any department of health must be based on this principle. You will recall that when Cobden was endeavoring to bring about a repeal of the Corn Laws, in a spirit of indignation with his colleagues in Parliament on the opposite side of the House he said that he was forced to the conclusion that the only way to get anything into the heads of the English people was to repeat it over and over again in just a little different language. This experience is not by any means limited to the English, it is the experience of all educators. However, I think we have failed in a great measure in the past through having kept our scientific knowledge for the most part within the precincts of our universities and laboratories. It is obviously essential that we democratize this scientific knowledge by translating it into terms that can be understood by the man in the street and the woman in the humblest home of our city.

There are various channels through which the public may be educated, one of the most important being by public addresses which should be delivered as far as possible by the Medical Officer of Health himself. Then there are newspaper talks, health bulletins, health leaflets, etc., but it must be borne in mind that there is a large number of citizens in every municipality who cannot read and a further number who can but do not read, and still others who read but do not think. Obviously the only way to get the information across to these people is by personal contact. I therefore feel that the most effective

means of disseminating public health knowledge is by public health nurses, who are rendering a valuable service in the homes. In their heart to heart talks with the mothers, they can explain the ways and means by which disease is transmitted and how it can be prevented, as well as a knowledge of the choice of foods in order to secure for the children a properly balanced diet at a minimum of expenditure. The nurse can also instruct the mother regarding the best ways of cooking and serving the food.

Probably one of the most practical demonstrations we have of educating the public is that in connection with the safeguarding of our milk supply. There are three points that are necessary to emphasize in this connection: first, that milk is the most valuable food we possess; secondly, that ordinary market milk unprotected has been responsible for the transmission of more communicable diseases than all other foods combined; and thirdly, that this valuable food can be made absolutely safe by a proper system of inspection that will secure a clean milk and then having that milk scientifically pasteurized. The history of the pasteurization of milk in America is rather interesting in this respect inasmuch as the first milk depots on the continent of America were established in New York city in the tenement house districts where milk scientically pasteurized was supplied to the poor children free of cost. This was done by a merchant prince, multimillionaire and public spirited citizen, Mr. Nathan Straus, on the advice of Dr. Abraham Jacobi and Dr. Rowland Godfrey Freeman, two of the most widely recognized authorities on the diseases of children on the American continent and with an international reputation. Under the guidance of Dr. Jacobi and Dr. Freeman, at a great expense to himself, Mr. Straus established and maintained these milk depots for years, and notwithstanding the indisputable evidence that they were able to produce on the reduction of infant mortality from gastrointestinal diseases alone, though these depots were established in 1892, it was not until 1909 that action was taken by the city of New York for the compulsory pasteurization of all milk not coming up to the standard of a certified milk. We had a similar experience in Toronto, as it required several years of intensive education before we succeeded in having regulations and ordinances passed requiring that all milk not coming up to the standard of a certified milk be scientifically pasteurized. Though the process of education is slow, yet the permanency of the results obtained fully warrants the efforts put forth.

THE PUBLIC HEALTH NURSE

The entrance of the Public Health Nurse into the field of preventive medicine has opened a new era in public health, inasmuch as most of the real, lifesaving problems in public health activities today have been made possible by the public health nurse, for instance, prenatal care, the presence of a nurse as the well baby clinics, and the follow up to the home, the presence of the public health nurse in the school and the following up of the cases in the home, and the tuberculosis work in connection with the tuberculosis clinics; here again her educational work as regards the prevention of tuberculosis in the homes is of inestimable value. Furthermore, the possibilities of hospital social service work being made a part of the general social service work of the department of health, the nurse acting as a mediator between the home and the patient in the hospital. In fact, I judge largely the efficiency of any organization of public health or administration of public health by the number of public health nurses they have.

In addition to this, we have in connection with the Department of Public Health in Toronto a social welfare division which investigates the administration of all institutions receiving grants from the city from the viewpoint of efficiency and serves in an advisory capacity to the Mayor and Council as regards the grants. In addition to this, they investigate all applicants to the Mayor's office for relief, making a careful study of each and every case, not only from the viewpoint of immediate relief, but also the possibilities of rehabilitation. This division works in close cooperation with all private social agencies in the city, acting in many cases as a clearing house and determining the cases should be handled by the city and those that should be handled by private agencies. This work is of extreme importance in all public health administration, inasmuch as at the very foundation of public health work is the solution of the social problem of the home. The revenue of the home being the only way by which we can decide whether or not the family can be properly nourished, properly clothed and properly housed, without which they are likely to have a lowered vitality and a lowered power of resistance and consequently a greater susceptibility to disease, the efficient administration of this division may often mean the difference between the families becoming an asset or a liability.

One will naturally conclude that this must mean a rather heavy expenditure. I refuse to call it an expenditure, but rather an investment, inasmuch as we are able to demonstrate by results that from the investment of this money the citizens get much larger dividends than any other that the municipality makes. For instance, Toronto's general mortality in 1909 was 15.8 per 1000, while in 1925 it was 10.2 per 1000, which means that with a population of a little over half a million Toronto is having over 2,500 fewer deaths every year than they would be having if the death rate of sixteen years ago still obtained. Toronto's tuberculosis mortality in 1909 was 102 per 100 thousand, while in 1925 it was just 46.5 per 100 thousand. Toronto's infant mortality in 1909 was 158.5 per thousand births, while in 1925 it was 60.2 per 1000 births. Toronto's typhoid mortality in 1909 was 48.7 per one hundred thousand; in 1925 it was 1.6. In addition to this, the control of a group of acute communicable diseases has been equally encouraging. For instance, the death rate in Toronto in 1909 from all the acute communicable diseases was 145 per one hundred thousand; in 1925 in was 25.3. It must be apparent, therefore, that public health administration has passed the experimental stage and that any municipality can within reasonable limitations have as much health as it is willing to pay for. One only requires to estimate what the saving of 2,500 lives means to a municipality every year, which means the additional saving of practically ten times that many cases of sickness, to appreciate fully that the money used in public health administration is an investment and not an expenditure.

Placenta Previa*

A. LOUISE McILROY, M.D., D.Sc.
London

(*Concluded from page* 416)

Packing the vagina, however, and version afford an opportunity before delivery of treating the collapse and shock from hemorrhage on ordinary lines, so as to strengthen the patient before the fetus and placenta are expelled. The method has some disadvantages for the fetus. During version the cord which is in a low situation may become prolapsed or entangled in the fetal parts and pulsation cease, or the buttocks by the efficiency of their pressure may abolish the circulation in the placenta and so cause stillbirth.

If the fetal heart ceases to be heard just after version has been performed, prolapse or strangulation of the cord has probably occurred. If it ceases during the progress of labor death is probably due to pressure on the placenta. Once hemorrhage is controlled by version, labor as a rule commences. This should not be hurried as the patient should be allowed to recover gradually from collapse if hemorrhage has been severe. Delivery should be allowed to take place spontaneously.

The practitioner should now be concerned with the prevention of postpartum hemorrhage, which can be effected by restoring the patient and therefore the uterus to a more normal condition. Salines, blood transfusion, etc., can be administered. Sedatives, such as morphine, may be given but with extreme caution for not only the patient's heart but also that of the fetus is weakened by hemorrhage. It is not advisable to give full pituitary extract as there is a risk of overstimulation of the uterus before delivery and consequent postpartum hemorrhage due to fatigue of the uterine muscles. It may be used in some cases in small doses to sensitize the uterus and bring on contractions where version has been performed and the onset of labor is delayed.

Postpartum hemorrhage does not occur so frequently as might be expected, especially when uterine contractions are well established before delivery. Its absence may also be due to the rapid expulsion of the placenta which usually takes place at a short interval after that of the birth of the infant. The placenta is usually of average size and weight.

DILATING BAGS

The use of dilating bags has been advocated in cases where labor has to be induced, and also to control hemorrhage. They are employed to lessen the risk to the fetus involved in version. Although in theory the use of a bag of the Champetière de Ribes type seems ideal, in practice it involves an element of risk to the patient and for the following reasons I have entirely abandoned its use.

It is not always at hand in emergencies. It is expensive and owing to the deterioration of the rubber it sometimes bursts when in position in the uterus. Owing to its complicated structure it is difficult to sterilize effectively. Its introduction requires the presence of a considerable degree of dilatation of the cervix. The chief objection, however, in cases of placenta previa is that when labor has commenced, the bag may be forcibly ejected by the uterine contractions, and the dilated lower uterine area is left unprotected by pressure. Severe hemorrhage may take place necessitating version for its control unless the presenting part of the fetus descends immediately to take the place of the bag. This descent does not always occur as the bag has a tendency to displace the portion of the fetus which is about to engage in the pelvis. Therefore, a patient who is being treated with a bag must have the close attendance of the medical practitioner in case such an emergency occurs.

When a dilating bag is introduced into the uterus, it must be inserted inside the amniotic cavity so as to avoid separation of the placental margin. In cases of complete placenta previa it must be introduced through the perforated placenta. The smaller balloons or rubber bags act as dilators of the cervix rather than as efficient compressors of the placenta.

Cases of incomplete placenta previa at term or in labor when first diagnosed may be treated by rupture of the membranes and by the application of forceps in vertex presentations when sufficient dilatation of the cervix is present. These cases as a rule give excellent results to both mother and infant but they are not a usual type.

Where the placenta is situated laterally the results of treatment are better than in those of the marginal variety. The chief point in the prognosis is the degree with which the placenta overlaps the internal os uteri.

Malpresentations may endanger the prospects of the child, but in premature cases they are not much of a complication. It must be borne in mind that Cæsarean section does not always mean a living child. If weakened by previous interference with its placental circulation an infant may not survive the sudden introduction to neonatal conditions and surroundings, for although we have no definite information on the subject labor must in some way gradually prepare the fetus for adapting itself to the changed conditions when it leaves the uterus. The prognosis of the child's life depends upon the amount of hemorrhage that has taken place.

Although in many cases the fetal heart sounds are still present on examination, the least interference may cause their cessation owing to the lowered resistance from loss of blood.

PART III.: CONCLUSIONS AND PRECIS OF FORTY-THREE CASES OF PLACENTA PREVIA

The substance of the foregoing paper has been based on the research upon the cases occurring in the Obstetrical Unit during the years 1921-1925.

*From The Obstetrical and Gynecological Unit of the London (Royal Free Hospital) School of Medicine for Women, University of London.

CONCLUSIONS

The cause of placenta previa is unknown.

The most probable theory is that the capsular portion of the decidua persists instead of the basal.

Recurrence of the condition at subsequent pregnancies is rare.

The lower uterine segment develops during the latter weeks of pregnancy and is stretched by the uterine contractions.

If the placenta is inserted completely or partially in this zone separation with consequent hemorrhage may occur.

The pregnant uterus is more sensitive when a menstrual period would have been due and contractions and hemorrhage are then more likely to occur.

Placenta previa occurs in about one in five hundred cases.

It is more frequent in multigravidæ than primigravidæ.

For clinical purposes it is classified into two groups, complete and incomplete. The latter comprises marginal and lateral types. The marginal is the most common.

Hemorrhage is the chief symptom. It varies from slight to severe and continuous recurrent attacks.

Sudden severe is worse than repeated hemorrhage. Except in rare cases where toxemia is present placenta previa occurs in healthy patients.

The diagnosis of placenta previa can be made from the abdomen if the placenta *souffle* is heard in the lower uterine zone. There is increased pulsation in the fornices, the cervix is softened, and if dilated the placenta may be actually palpated.

The prognosis is serious for both mother and child. Maternal mortality averages about six per cent. and is due to hemorrhage shock or sepsis. The fetal mortality at birth is almost seventy per cent. The survival rate is low. The chief causes of fetal death are antenatal shock, prematurity and operative interference. About seventy per cent. of infants are born premature.

Treatment is a choice between expectant and active interference. Expectant treatment should only be carried out if the placenta is incomplete, or the diagnosis doubtful.

The patient must be kept under careful observation with facilities for immediate operative measures if necessary.

In complete placenta previa the condition should be actively dealt with as soon as it is diagnosed. Cæsarean section is the only chance for the infant in these cases. It is contraindicated in premature cases with a dead fetus, or if patient is collapsed.

Version, although it endangers the life of the fetus, is the best possible method for maternal safety.

If the cervix is insufficiently dilated to admit two fingers it should be dilated by packing the vagina. Rapid dilatation or delivery is contraindicated.

Every precaution should be taken to restore the patient when in a state of collapse before delivery occurs.

Owing to hemorrhage and lacerations sepsis is probable in cases of placenta previa.

I am indebted to my former assistants, Dr. Charlotte Houlton and Dr. Gertrude Dearnley, and to my present assistants, Dr. Edith Hall and Dr. Gray, for their help in the treatment of these cases.

CASE REPORTS

I present below reports of forty-three cases of placenta previa occurring in the obstetrical unit.

COMPLETE PLACENTA PREVIA—NINE CASES

CASE I.—Multigravida 3, aged forty-two, pulseless on admission, one severe hemorrhage in six hours; in labor twelve hours; no fetal heart sounds. Vertex presentation; cervix three fingers; version, foot extraction; collapse treated; delivery two hours; stillbirth; placenta, five minutes; puerperium satisfactory.

CASE II.—Primipara, aged thirty-six; two and one half hour's severe hemorrhage; in labor; fetal heart sounds; vertex cervix two fingers; no evidence of toxemia; Cæsarean section; no attempt at respiration; stillbirth; membranes necrotic. Patient suddenly collapsed from hemorrhage four hours after operation, and died in an hour.

CASE III.—Primipara, aged thirty-two; old gonorrheal infection; no hemorrhage. Diagnosis from palpation of placenta p. v. at thirty-eighth week. Patient admitted for observation: some hemorrhage; antiseptic treatment of cervix; Cæsarean section, because of patient's wishes and an old infective cervix, and probable future sterility; live birth; slight pyrexia in puerperium. Recovery was satisfactory.

CASE IV.—Primipara, aged thirty-two; contracted pelvis, gonorrhea, complete placenta previa, no hemorrhage. Child born alive; some pyrexia during recovery.

CASE V.—Primipara, aged thirty-one; twenty-eighth week; criminal abortion attempted several times, always followed by severe hemorrhage; hemorrhage slight for four days; labor three days; no fetal heart sounds; vertex presentation; cervix two fingers; fetal head soft; membranes ruptured; perforation; macerated fetus delivered five hours later; placenta immediate; puerperium satisfactory.

CASE VI.—Multipara 3, aged thirty-six; twenty-eighth to thirtieth week; severe hemorrhage four hours; slight attack one month before; fetal heart sounds; breech presentation; cervix one finger. Packed twelve hours, foot extraction, cord pulseless on delivery; stillbirth; placenta one hour, battledore, old blood clot; puerperium satisfactory.

CASE VII.—Multipara 3, aged twenty-three; thirty-fourth week; severe hemorrhage one month before; diagnosed at antenatal clinic by souffle and vaginal examination; no hemorrhage; admitted, fetal heart sounds; cervix three fingers; breech presentation; foot extraction; delivery seven and one half hours; cord pulseless; stillbirth; placenta immediate; puerperium satisfactory.

CASE VIII.—Primipara, aged thirty-three; breech presentation; thirtieth week, in labor; hemorrhage not profuse; placenta perforated and leg brought down; stillbirth; recovery.

CASE IX.—Multipara 5, aged thirty-two; thirty-fourth week; hemorrhage severe, previous hemorrhage at thirtieth week; breech presentation; vaginal pack two hours, leg brought down; stillborn (cerebral hemorrhage postmortem); recovery.

INCOMPLETE PLACENTA PREVIA—TWENTY-SEVEN CASES

CASE X.—Primipara, aged thirty-three; recurrent slight hemorrhage; some hemorrhage on examination at antenatal clinic; admitted for observation at thirty-fourth week; no hemorrhage; readmitted in labor at term, some hemorrhage; vertex presentation; spontaneous delivery; live birth; some pyrexia due to perineal laceration; recovery satisfactory.

CASE XI.—Multipara 2, aged thirty-five; hemorrhage slight six weeks before; severe hemorrhage at term; not in labor; blanched; fetal heart sounds; vertex presentation; cervix two fingers; souffle above symphysis; packed version; labor began; no fetal heart sound; delivery three hours; stillbirth; placenta ten minutes; slight postpartum hemorrhage; puerperium satisfactory.

CASE XII.—Multipara 6, aged thirty-three; admitted for slight hemorrhage two days before labor; considerable hemorrhage at labor; cervix two fingers; vertex presentation; no fetal heart sounds; version foot extraction; delivery four and one half hours; child breathed but did not survive; puerperium satisfactory.

CASE XIII.—Multipara 2, aged forty-one; hemorrhage slight on admission, severe on examination; not in labor; fetal heart sound; vertex presentation; cervix one finger; quinine given, membranes ruptured; packed; head pushed down; delivery nine and one half hours; live birth; placenta thirty-five minutes; puerperium satisfactory.

TWENTY-ONE PREMATURE CASES

CASE XIV.—Multipara 2, aged thirty-two; thirty-eighth week; three attacks of hemorrhage at four week intervals; severe hemorrhage on admission; not in labor; fetal heart sound; vertex presentation; cervix two fingers; version. Cord prolapsed; delivery twenty hours; stillbirth; placenta immediate; battledore and velamentous; puerperium satisfactory.

CASE XV.—Multipara 3, aged thirty-seven; thirty-second week; severe hemorrhage three hours; not in labor; fetal heart sound; breech presentation; cervix one finger; packed twelve hours; repacked twelve hours as hemorrhage recurred; version delivery; one and one half hours; live birth; survived fourteen hours; placenta immediate. Temperature rose fourth day, coliform infection; patient died on the fifteenth day of septic pneumonia.

CASE XVI.—Primipara, aged twenty; thirtieth week; sudden hemorrhage four hours after ol. ricini; not in labor; fetal heart sound; vertex presentation; cervix one finger; packed; labor, pack removed; breech, foot extracted; delivery one hour; live birth, survived two hours; placenta immediate; puerperium satisfactory.

CASE XVII.—Multipara 3, aged thirty-two; thirty-second week; sudden severe hemorrhage; placenta not felt, admitted for observation; no hemorrhage, discharged. Readmitted seven days later, severe hemorrhage; not in labor. Fetal heart sound; placenta felt; cervix two fingers; vertex version; foot extraction; labor began, delivery seven and one half hours; live birth; placenta twenty minutes; puerperium satisfactory.

CASE XVIII.—Primipara, aged twenty; twenty-eighth week; sudden hemorrhage on micturition; not in labor; cervix closed; transverse presentation; packed; labor one and one quarter hours; version foot extraction; delivery nine hours; cord pulsating, child did not survive; placenta ten minutes; puerperium satisfactory.

CASE XIX.—Primipara, aged twenty-five; thirtieth week; intermittent hemorrhage; six days, said to be due to lifting heavy weight; not in labor; fetal heart sound; labor eight days later; cervix two fingers; vertex presentation; version, foot extraction; delivery two and one half hours; live birth, survived two days; placenta twenty minutes; puerperium satisfactory.

CASE XX.—Multipara 7, aged thirty-six; thirty-fourth week; hemorrhage several hours; not in labor; cervix one finger; packed twelve hours; repacked as there was no dilatation; labor in twelve hours; fetal heart sound; version; six hours later no fetal heart sound; delivery eight and one half hours; stillbirth; placenta five minutes; puerperium satisfactory.

CASE XXI.—Multipara 2, aged twenty-six; thirty-fourth week; hemorrhage one hour; blanched; not in labor; fetal heart sound; cervix two fingers; vertex presentation; version; foot extraction; delivery five hours later; live birth; survived twenty-four hours; placenta ten minutes; puerperium satisfactory.

CASE XXII.—Multipara 2, aged thirty-five; thirty-eighth week; hemorrhage twenty-four hours; not in labor; cervix two fingers; packed, expelled by pains in ten hours; breech presentation; fetal heart sound; delivery one hour; live birth; placenta immediate, velamentous; puerperium satisfactory.

CASE XXIII.—Multipara 5, aged forty-one; thirty-eighth week; hemorrhage several hours, not in labor; fetal heart sound; vertex presentation; cervix closed; sudden hemorrhage on examination; packed twelve hours; version foot extraction; delivery two hours; live birth; placenta ten minutes; puerperium satisfactory.

CASE XXIV.—Multipara 2, aged thirty-two; twenty-eighth week; considerable hemorrhage twenty-four hours; four weeks before; severe six days before admission; packed by doctor and kept in bed four days; hemorrhage recurred, admitted, not in labor; fetal heart sound; cervix one finger; breech; foot extraction; delivery four hours; live birth, survived twenty-four hours; placenta ten minutes; puerperium satisfactory.

CASE XXV.—Primipara; aged twenty-five; thirtieth week; some hemorrhage week before at antenatal clinic; placenta not felt; sent home to rest; severe hemorrhage next day; admitted; no placenta felt; under observation ten days; sent home; six days later readmitted, hemorrhage for six hours; no fetal heart sound; cervix three fingers; placenta felt; transverse, in labor, foot extraction; delivery six and one half hours; stillbirth; placenta ten minutes; puerperium satisfactory.

CASE XXVI.—Multipara 1, aged twenty-seven; thirty-fourth week; severe sudden hemorrhage one and one half hours; fetal heart sound; transverse cervix two fingers, in labor; version, foot extraction; no fetal heart sound; delivery ten hours; stillbirth;

placenta five minutes, battledore; breast abscess in puerperium.

Case XXVII.—Multigravida 8, aged forty-three; thirty-eighth week; hemorrhage at thirty-fourth week in a previous pregnancy; admitted having had severe hemorrhage for four hours; irregular hemorrhages six weeks; no placenta felt; not in labor; observation two days; no hemorrhage; awakened two a. m. in a pool of blood; fetal heart sound; placenta felt; version; foot extraction; cord prolapsed; delivery five hours; stillbirth; placenta ten minutes; puerperium satisfactory.

Case XXVIII.—Primipara, aged twenty-seven; thirty-second week; hemorrhage slight; no fetal heart sound; twins; placenta felt p. v. cord prolapsed after rupture of membranes had occurred; spontaneous delivery; stillbirth, puerperium satisfactory.

Case XXIX.—Multigravida 2, aged thirty-seven; twenty-four week; history of abortions and toxemia; no fetal heart sound; transverse; placenta felt p. v. hemorrhage recurred; admitted from district as placenta previa; in labor, cervix fully dilated; foot extraction; delivery fifteen minutes; stillbirth; placenta; five minutes; puerperium satisfactory.

Case XXX.—Multigravida 5, aged thirty; twenty-eighth week; hemorrhage before admission; toxemia, albumin; placenta felt; not in labor; began in two hours; more hemorrhage; cervix dilating; version; foot extraction; delivery two hours; stillbirth; placenta five minutes; puerperium satisfactory.

Case XXXI.—Multigravida 8, aged forty-one; thirtieth week; sudden hemorrhage two weeks before; hemorrhage severe on admission; not in labor; vaginal pack, hemorrhage, version, leg brought down, pulse very rapid, blood transfusion, etc. Patient died undelivered as she was in a state of collapse on examination.

Case XXXII.—Multigravida 1, aged thirty-seven; thirty-eighth week; coli infection of bladder; hemorrhage on examination; Cæsarean section as head was not engaged and fetus large; alive; recovery satisfactory.

Case XXXIII.—Multigravida 3, aged thirty-two; severe hemorrhage for five days, in labor, cord and arm prolapsed on admission; fetus dead; delivery by decapitation; puerperium febrile, recovery.

Case XXXIV.—Multigravida 7, aged forty-two; cardiac complications, hemorrhage, fetal heart sound not heard; version, leg brought down; stillbirth; recovery.

LATERAL PLACENTA PREVIA

Case XXXV.—Multigravida, aged thirty-two; considerable hemorrhage three days; no fetal heart sound; cervix two fingers, in labor, membranes ruptured; spontaneous delivery sixteen hours; stillbirth; some p. p. h.; puerperium satisfactory.

Case XXXVI.—Multigravida 3, aged thirty-eight; slight hemorrhage; in labor, membranes ruptured; delivery live birth; placenta ten minutes; puerperium satisfactory.

Case XXXVII.—Multigravida 4, aged forty-five; thirty-fourth week; hemorrhage twenty-four hours; intermittent for four weeks; fetal heart sound; placenta souffle above symphysis; not in labor; vertex; cervix two fingers; version, foot extraction, some hemorrhage; delivery three hours; stillbirth; placenta five minutes; puerperium satisfactory.

Case XXXVIII.—Multigravida 7, aged thirty-three; thirty-fourth week; hemorrhage intermittent two weeks; not in labor; placental souffle; fetal heart sound; cervix one finger; vertex; hemorrhage, manual dilatation; version; foot extraction; delivery six hours; live birth; placenta 10 minutes; puerperium satisfactory.

Case XXXIX.—Multigravida 1, aged twenty; thirty-sixth week; slight hemorrhage; in labor; fetal heart sound; vertex, forceps; live birth; placenta ten minutes; puerperium satisfactory.

Case XL.—Multigravida 3, aged forty; twenty-eighth week; considerable hemorrhage; no fetal heart sound; not in labor; vertex; cervix closed; packed; labor four hours later; version five hours later; delivery twelve hours; macerated fetus; placenta ten minutes; puerperium satisfactory.

Case XLI.—Multigravida 8, aged forty-three; thirty-eighth week; hemorrhage from thirty-second week, not in labor, version, leg brought down, stillborn; recovery.

Case XLII.—Multigravida 7, aged thirty-three; thirty-second week; hemorrhage for some weeks slight; fetal heart sound heard; hemorrhage intermittent during observation for four days; cervix dilated digitally, version, leg brought down, child alive and survived; recovery.

Case XLIII.—Multigravida 2, aged thirty-one; thirtieth week; intermittent hemorrhage from twenty-sixth week; cervix dilated, membranes ruptured, spontaneous delivery; child survived forty-eight hours; recovery.

The Principles in the Treatment of Cancer*

RICHARD J. BEHAN, M.D.
Pittsburgh, Pa.

It is difficult to begin a paper on the treatment of cancer because at the present time cancer does not offer to us definite conclusions as to its etiology or the physiological changes controlling its development. If it were an ordinary type of disease of which the cause was known and for which a definite routine of therapy could be defined, the treatment might be divided into, first, the prophylactic or preventive treatment; second, the active treatment, and third, the treatment of sequelæ. Since the causative factor is unknown, and the biology of its development is but hazily postulated, it is difficult scientifically to formulate for cancer a system of therapeutics as is done in the modern methods of treating other types of disease.

*Read before the Buffalo Academy of Medicine, November, 1925.

PROPHYLAXIS

There is no doubt that trauma, especially that which is long continued and which is repeated with about equal intensity in the same location, is a potent cause of cancer. It is likely that injuries occupy a higher place as an etiological factor in cancer production than is usually assigned to them. It is sometimes very difficult to correlate the trauma to the cancer which follows, because there usually is such a long period of time elapsing between the trauma and the appearance of the cancer that the relationship between the two is obscured. Villata found that 2.23 per cent. of 762 cases of cancer gave a definite history of a single severe trauma. The interval between the trauma and the onset of the disease ranged from a few weeks to several years.

However, that a relationship between trauma and cancer does exist, cannot be doubted by anyone who has interested himself to a sufficient degree in the etiology of cancer. Trauma may be either mechanical, chemical or thermal. A mechanical cause of cancer is present in those who have bad teeth or misplaced, badly fitting plates. Irritation is also due to pressure from collar buttons in cancer of the neck and in irritation of glasses on the bridge of the nose. We find irritation and cancer arising from thermal agents, such as the cancer in the natives of Kashmir, who carry charcoal for heating purposes in wicker baskets over the abdomen; we find cancer of the esophagus in the Japanese who continually eat hot rice. Peculiarly, it is found only among the men who are served with the rice when it is hot; the women eating the cold rice. There has been a case in which a man who was a tinner had a cancer in the forearm, developed on a chronic dermatitis. This man, while at work, continually had the forearm (on the ulnar side) exposed to the heat of a furnace. There are also the well known examples of irritation cancer of the lip in pipe smokers. We also know that radioactive substances will cause cancer and have examples of it in cancer on the parts exposed to the rays in radium and x ray workers.

That irritating substances may of themselves cause cancer is exemplified in the cancer found among shale workers in the north of England; the cancer of paraffin workers and of those who work with arsenic, etc. Irritation from parasites will also cause cancer, as we find the bilharzia producing cancer of the bladder. Aniline workers have cancer in the same location. Cancer is also produced by the irritation which is normally present in scar tissue, especially when the scar is in a location subject to irritation, as at the cervix uteri.

It is likely that irritation of itself produces some change in the irritated tissues which lead to the cell proliferation. Therefore, as a prophylactic measure all such irritations should be removed.

Glands of internal secretion, especially the hypophysis, may have influence upon the development of cancer. This has been experimentally determined by Seele, who shows that the time of incidence of a tar carcinoma in rabbits is definitely retarded by the injection into these animals of a preparation of the anterior lobe of the hypophysis. However, how these facts can be used for the elaboration of a method of protection against cancer, either curative or prophylactically, is as yet undetermined.

According to findings of the Imperial Cancer Research, 1922, repeated and prolonged exposure to the x ray produces the same symptoms as a Vitamine B deficiency, which in time produces progressive diminution in blood platelets. It also causes a diminution in lymphocytes. We know that in carcinoma, usually the lymphocytes are increased. However, here again enters a contradictory factor, for Simmons has recently shown that in mice, those which had the most marked lymphoid proliferation and the most abundant lymphocytes had carcinoma develop and grow apparently unhindered. It is also interesting to know that Itchichawa's injection of small amounts of olive oil into mice, intraperitoneally, produced an immunity to cancer. These animals exhibited marked lymphocytosis. Lymphocytes, according to Grobly, are the natural defenses of the organism against cancer. He thinks that the small cell infiltration about a cancer area carries nucleoproteid to the cancer cells, as found in the disintegration of cancer cells in the lymphoid tissue. He finds that cell nests which are cut off from the main bodies are beginning to cytolyze so that he thinks that the round cells infiltration not only has the effect of cutting off the nourishment to the cancer cells, but acts against them. Increase of the lymphocytes is also thought by many to indicate a tendency to resistance. This action of the lymphocytes possibly may explain the deleterious action in some cases of a local hypertoxic dose of x ray because the high dosage of the x ray will destroy the lymphocytes which apparently may be one of the protective agents of the body against the carcinoma.

A pertinent fact is that the patients in whom the lymphocytes are highest in proportion to the total blood count do best under any type of cancer treatment. Also, from recent studies, it appears that the lymphocytes may vary with the plasmic acidity; the greater the acidity, the greater the percentage of lymphocytes. Smaller doses of x ray are more beneficial in stimulating lymphocytic reaction than are the large toxic doses. The seemingly contradictory conclusions of students of the cancer problem, render difficult the formulation of a definite and logical therapy yet, if a man with an encyclopedic mind and the faculty of clear and logical deduction should interest himself in the cancer problem, he might, from the vast array of experimental evidence which is now available, be able to draw some definite conclusions as to the actual causative agency. When this agent is known prophylactic protection may be instituted against it and active destruction when it is present may be undertaken, with fairly definite assurance of success. Until such time, we must use such means as are at hand must be used in our struggle against cancer. This now leads me from a discussion of the theoretical into the field of the practical.

ACTIVE TREATMENT

The active treatment of cancer may be divided into local destruction and constitutional treatment. Local destruction at the present time seems to be the only absolute way of curing cancer. The agent instrumental in causing local destruction varies as to location of cancer accessibility of growth and availability of means of treatment. The agents are, first, caustics; second, the cautery, that is, the hot iron; the electric cautery or the fulguration apparatus. We may use

for the same purpose, i. e., to cause destruction of the growth, radioactive substances such as radium and the x ray. Radium may be either applied in the form of its salt or by means of emanation enclosed in capillary tubes. The x ray that is used may be of either low or high voltage, depending upon the location of the growth and the means at the disposal of the therapeutist.

Local destruction is best and most thoroughly carried out by direct excision of the growth, either by the knife, by the hot cautery or by the socalled radio knife or cold cautery, by which there is no charring of the tissues. Surgery may also be used as an accessory measure in order to produce changes and alter conditions which may have an influence upon the growth. For instance, the ligation of the blood supply, fascial lymphatic excision, sympathectomies and short circuitive operations such as gastrostomies in carcinoma of the esophagus or in carcinoma of the alimentary tract above the stomach; jejunostomy in carcinoma of the stomach; enterostomy in carcinoma of the bowel and colostomy in carcinoma of the rectum and anus.

It may be held as an axiom that no matter how the local growth is destroyed, if the destruction is thorough, it is of value. However, the irritation accompanying the destruction should be as mild as possible, because we should not forget that localized irritation of itself is the most potent cause of cancer, and it is likely true that the less the irritation produced by the removal of the growth, the less is the growth likely to recur. There is considerable fear of the implantation of cancer cells in a wound when the neoplasm is excised by the knife. That such implantation is possible, I have demonstrated in the treatment of an inoperable carcinoma by means of alcohol, with the idea of producing a protective wall of fibrous tissue. Alcohol was injected peripherally around the tumor. In the path of the needle in three instances, carcinoma metastases developed. There is no doubt that I was instrumental in carrying the cancer cells from their former location into the new area in which they developed.

In the accessory treatment of carcinoma, the surgeon should aim, first, to conserve the resources of his patient. As the carcinoma cells are very active in development and require a considerable amount of nourishment, much more than the normal surrounding tissue cells, it is logical to assume that curtailment of the blood supply to the part would be a useful measure. With this object in view, in thirty-five cases of carcinoma of the face, I have on the involved side, ligated the external carotid artery and dissected and removed the fascia, and the submaxillary gland, and in ten days have ligated the external carotid artery on the opposite side. At the time of the ligation of the second vessel, the remaining fascia of the submaxillary triangle of the neck, with the accompanying lymph glands was removed. The rapid diminution in size of the tumor has been remarkable even after ligation of one external carotid artery. The beneficial effect upon the tumor may be partly ascribed to the reduction of the inflammation edema which favors cancer growth. Bainbridge noticed similar results. There is immediate cessation of pain; the foul discharges are lessened and the patient is greatly improved. I was under the impression that the beneficial results were due to the lessening of the blood supply, although I was aware of the fact that the nutrition of the face and of the site of the local disease even after tying of both external carotids did not seem to be especially affected. The easing of the pain I also ascribed to the decrease in the edema with consequent reduced pressure upon the nerve filaments in the involved area. This may not be entirely true. It is likely that in ligating the external carotid arteries, I blocked the accompanying sympathetic nerve irritation and thus reduced the edema in the affected area. Analogous is the improvement noted in edema of the feet with ulceration when femoral arterial sympathectomy is performed.

These facts are extremely interesting and perhaps may indicate to us some causal relationship between sympathetic nerve irritation and cellular overproduction. Turner (1) states that cells when they lose their function do not necessarily die but if they have nourishment and the external stimulants of growth, they continue to live and multiply. If the central control through the sympathetic to the cells is cut off, the cells continue to be influenced by function and they live and multiply indefinitely.

How curtailment of the blood supply may act upon the tumor in a beneficial manner is difficult to say. It is known that cancer tissue will continue to grow in a person who is starving; in other words, the active cancer cells will use the tissues of their host for their nutrition, so that while the tissues of the host become less in volume and functional activity decreases, the cancer tissue continues to develop. However, there is an added factor in starvation which may not be beneficial for cancer tissue proliferation and that as starvation progresses the tissues become less alkaline and more acid in reaction. It seems to be necessary for the continuation of the growth of carcinoma cells, that the media in which they are should be acid. Therefore, when we reduce the nourishment of the tissue of the face by ligating the external carotid arteries, and at the same time as is usually the case, the superficial and some of the deep veins are ligated, we block off from this area of the face the blood supply and produce starvation acidosis. If this is so, we should then supply locally some counteracting measures. This we have attempted to do with indifferent success by surfusing through the facial artery the tissues of the face on the same side as the tumor with five per cent. solution of sodium bicarbonate. Ligation of both internal iliacs in carcinoma of the uterus apparently has produced marked benefit. *Ligation of the blood supply prior to radiation seems to enhance the beneficial effects of the radiation.* The ligations of themselves give no permanent benefit but are adjuvants to other therapy; particularly x ray and radium. Ligation of the blood supply also renders the danger of hemorrhage in the large ulcerating tumors of the face and tongue less probable.

Excision, however, in all cases where possible, without too great danger to the patient and extensive deformity from tissue destruction, should always be done.

In our work, the greatest part of the tumor is resected by the endotherm, care being taken, however, not to use this knife in too close proximity to important vital parts. Here a sharp dissection with a cold

knife is done, although Wyeth even here recommends the endotherm. In our surgical operations, we have thought wise after removal of the growth, to form a barrier of resisting cell tissues, fibrous in character, in the lines of direction in which the cancer may advance. For this purpose we implant peripherally, where it is possible, seeds of radium emanation of one half m.c. each. In cancer of the breast, I try to place them at the points of emergence of the vessels in the intercostal spaces, especially near to the upper surface of the lower rib. I have also inserted them in close proximity to the large vessels and the nerves of the neck, but have always placed between them and the vessel or nerve, a small piece of muscle, one cm. in diameter, so that the radium seed does not lie directly upon the vessel or the nerve.

Preliminary to surgical removal röntgen radiation is usually given for the purpose of production of limiting fibrosis in addition to whatever direct destruction of the cancer cell may occur.

If the tumor is of the face, cheek or of the throat, or of the tongue and is rather large and requires extensive radon application or extreme radical surgery. Gastrostomy is made thus relieving the upper portion of the alimentary tract of all irritation which food particles, heat and cold, have upon the denuded and diseased tissues of the mouth or throat.

(To be concluded)

Protein Therapy in Pelvic Infection

HARRY PIKE, M.D.

New York

In view of the recognized value of foreign protein injections, especially of milk, in the treatment of arthritis and other infections, it was a natural sequence that this method of treatment should be tried by the gynecologist. But it was only within the last five years that it was seriously considered in this country as a means of combating pelvic infection without resorting to mutilating operations.

Petersen (1), in his interesting book on protein therapy and nonspecific resistance, recounts the fascinating history of protein therapy. It grew out of the serum and vaccine therapy prevailing during the last thirty years. The basic principle in serum and vaccine therapy is the relief of disease by specific means directly related to the disease. But protein therapy rests on a nonspecific basis. In other words, its basic tenet is that many infectious diseases may be relieved by the administration of nonspecific substances not directly related to the infection itself.

In America, Gellhorn (2) in 1922 introduced the protein therapy of pelvic infections. In ten of his cases of female gonorrhea, six patients were cured completely and two improved by this treatment. Gellhorn prefers milk injections to other foreign proteins. He believes that the protein substances, introduced intramuscularly, subcutaneously, or intravenously, have the faculty of stimulating the cells of the body to greater physiological activity; that is, of "activating the protoplasm." All the cells feel this rejuvenating influence, but especially those that have been damaged and depressed by infection.

According to Gellhorn, it is mainly the tubes, the uterus, and possibly the bladder to which this treatment should be directed. The ovaries seem to remain refractory, and gonorrhea of the cervix does not appear to be favorably influenced. These organs, in Gellhorn's opinion, should be treated by other measures. In general, foreign protein therapy brings about absorption of exudates but has no influence on adhesions.

Simon (3) in 1922 reported favorable results with foreign protein injections in twenty-six cases of septic puerperal affections and thirty of febrile abortion. His experience led him to recommend this form of treatment of puerperal sepsis and especially in febrile abortion.

Mohler (4) in 1925 reported success in the treatment of ten cases of pelvic infection with milk injections. His series included five cases of salpingitis and two of pelvic peritonitis. The patients were given five or six injections of milk at intervals of one week. In every case, the patient showed definite general improvement and the pain was diminished. A gain in weight, improved appetite, and an abatement of the secondary anemia were noteworthy.

HOW BENEFIT IS ACCOMPLISHED

The nonspecific protein reaction is diphasic in character. The first phase is marked by an intensification of the symptoms of the disease, both constitutionally and locally; the second, by improvement and reconstruction. General euphoria, a diminution of both local and systemic symptoms of the disease, and sometimes a complete disappearance of the lesions occur during this stage.

When an injured cell is restored to its original form and functions, it passes through a gradual series of morphological changes. These changes, which have repeatedly been demonstrated histologically, are of such a nature as to suggest a process of recharging the cell with energy. The probable explanation of the benefit following nonspecific protein therapy is that it acts in just this way; that is, to recharge the cells with energy.

Experience has taught that various physical agents, such as fresh air, sunlight, water, heat, and other means of producing hyperemia, exert a powerful influence on the cells of the body. However, none of them appear to be quite so potent as foreign protein injections.

Whatever the ultimate explanation or theory for the beneficial results that have been observed after nonspecific protein therapy, it will suffice, for the present, to point out that the depleted cells are recharged, as has been demonstrated histologically. By this means they are enabled to resist successfully the

invasion of pathogenic microorganisms. Rejuvenated, as it were, the cells develop strong antibacterial and antitoxic properties, and the phagocytic activity of the leucocytes is greatly increased. At the same time, the local metabolism is intensified. As a result of all these favorable reactions, collections of pus may be absorbed and the integrity of the affected tissues restored to normal.

The application of protein therapy to the treatment of gonococcal infections of the fallopian tubes is an excellent example of the benefit that may accrue from measures that enhance local resistance. If the stimulation of the affected cells is sufficient and the invading organisms suffer a temporary lowering of their virulence, the result is an immediate victory for the defending tissues.

Likewise, in puerperal sepsis, an increase in tissue resistance may be the factor that decides in favor of recovery. From the original site of infection, the pathogenic microorganisms spread by way of the lymphatics and blood stream to invade the entire body. If the cells of the body are brought to the highest peak of antibacterial efficiency by means of foreign protein injections, their chance of eliminating the infection, or at least of localizing it where it will be amenable to surgical procedures, will be increased proportionately.

Petersen (1), and also Lendig (5), list various protein substances that have been used experimentally and clinically to increase nonspecific resistance. They include milk, egg albumin, normal blood, immune serum, antitoxins, cerebrospinal fluid, pleural fluid, and other substances. For practical purposes, milk injections have been found most satisfactory.

HOW MILK INJECTIONS ARE GIVEN

In my earlier work I used whole milk, sterilized either in an autoclave or by boiling for ten minutes. Later, I have used aolan, which I prefer. This is a fat free, sterile milk, furnished in ampules and specially prepared for nonspecific protein injections.

The gluteal region is the best site of injection. A long needle should be used and the injection made deep, as in the case of the mercury injections for syphilis.

The initial dose is five c. c.; the following doses, ten c. c. The injections are given at intervals of from three to five days, according to clinical improvement and the severity of the reaction.

As a rule, a general reaction follows the first injection in five or six hours. A mild chill and moderate fever are the rule. However, the temperature may rise to 104° F. and the fever be so severe as to give rise to a sense of euphoria, similar to that which occurs during the peaks of fever in tuberculosis. The patient looks and feels well notwithstanding the violence of the reaction. The leucocyte count may be increased to from twenty thousand to thirty thousand cells

Clinical improvement may begin after the second injection, sometimes even after the first. In other cases, however, more treatments may be required before the symptoms start to abate.

REPORT OF CASES

Case I.—L. B., female, married, aged thirty, gave a history of gonorrheal infection five years previously. Typical gram negative diplococci of coffee bean shape were found in the vaginal smears. Pelvic examination disclosed evidences of ascending gonorrheal infection. Bilateral pyosalpinx and pelvic peritonitis were present.

The patient was given eight injections of sterilized milk. At no time was there any severe reaction. The only other treatment used was the application of dry heat. The patient made a complete recovery and has been free from all disturbance for two years.

A remarkable feature of this case was the fact that the cervical gonorrhea cleared up without local treatment. Smears from the urethra and cervix have been negative for gonococci. In Gellhorn's experience, gonorrhea of the cervix was not favorably influenced by nonspecific protein therapy. In the present case, the milk injections unquestionably saved the patient from the necessity of a mutilating operation and gave a much better result than surgery could have attained.

Case II.—T. M., married, aged twenty-six, believing herself to be pregnant, tried to induce an abortion by inserting a catheter into the uterus. She was admitted to the hospital on September 10, 1925, with chills, a temperature of 105° F., and a pulse of 140. The white blood cell count was 25,000 cells. On examination I palpated a mass in the right side of the pelvis and bulging and fluctuation in the culdesac of Douglas.

After several milk injections there was complete absorption of the pelvic exudate. In this case the early use of protein injections, that is before exhaustion had set in, promptly checked the progress of the infection. The favorable result in this case of febrile abortion was similar to those mentioned in Simon's report. It appears that in cases of febrile abortion, the stimulation of the cells of the body produced by milk injections checks the progress of the infection, localizes the various embolic metastases, and favors the speedy circumscription of localized abscesses, thereby preventing the formation of secondary foci and generalized sepsis.

CONCLUSIONS

1. Nonspecific protein therapy is a valuable means of increasing the resistance of the tissues to infection, localizing infective foci, and preventing the development of general sepsis.

2. In the treatment of pelvic infections, especially gonorrheal involvement of the fallopian tubes, pelvic peritonitis, and febrile abortion, nonspecific protein treatment frequently gives results better than those of surgery.

3. Either milk sterilized in an autoclave or by boiling for ten minutes or aolan is the most suitable preparation for use.

Right Diaphragmatic Eventration, Accompanied by Cardiospasm as a Reflex of Malignancy at the Cardia

MEYER GOLOB, M.D.,
New York

Our chief interest in this case concerns itself, not with cardiospasm as a reflex of malignancy, but with the eventration of the right diaphragm by the hepatic flexure of the colon. For, although eventration of the *left* diaphragm by viscera such as the stomach and colon is anatomically accountable and is met with frequently in medical literature, eventration of the *right* diaphragm by the proximal colon anterior to the liver, is, I believe, a rare finding, and as such worthy of special report.

The late Dr. Aronson makes mention of an occurrence of right eventration while describing a case of Hirschsprung's disease. "The curious feature," he remarks, "was that the dilatation was coincident with eventration of the diaphragm on the right side rather than on the left." In looking for a cause accounting for the right side eventration, he dwells on the fact that the symptoms persisted for only two years, and were felt directly subsequent to the injury sustained by falling off the car in a manner which inflicted violence to the right side.

In the case under discussion, however, a history of an injury or a disease affecting the motor columns of the cervical cord and in consequence the phrenic nerves which supply the diaphragm, is conspicuously absent. It is therefore reasonable to assume that the case is purely congenital, and that eventration may be symptomless and discoverable only accidentally. This accords with the findings of Carman, that "Elevation is usually, if not always, congenital or due to inherent weaknesses."

The relative infrequency of an occurrence of right side eventration may be gathered from a comparison published by Eppinger in 1911, and quoted by Aronson:

Type	*Right side*	*Left side*
True hernia	21	53
False hernia	34	527
Eventration	2	15

Thus it may be seen that the ratio of eventration to hernia is one to thirty-seven, and that of right eventration to left is one to seven and a half.

FIG. 2.—Technic taken for esophagus, with overlapping of esophageal shadow on proximal colon, due to high position of the latter.

CASE REPORT

CASE.—S. L., aged fifty-seven, a peddler; married; family history and previous personal history irrelevant.

The salient features of the case were as follows: Dysphagia of one year's standing, growing progressively worse in the last two months, affecting both liquids and solids, though less marked with liquids. Vomiting in mouthfuls (esophageal vomiting). Constipation since childhood, but worse in past few months (starvation constipation). Appetite, singularly good. Evidence of weight loss, the only outstanding fact in the physical examination. Esophageal intubation twenty-two inches from the incisor teeth recovered food free from gastric juice. Fluoroscopy of the chest revealed the right diaphragm elevated and its convexity increased as if pushed up by the hepatic flexure of the colon which was capped with gas. Arch of the diaphragm showed the respiratory movement. Radioscopic examination with the opaque meal showed complete obstruction at the cardia with marked dilatation above that point. The epicardia was smooth in outline, such as is seen in cardiospasm. However, administration of belladonna to physiological effect did not bring about passage to the contrast meal. Esophagoscopic examination by Sidney Yankauer revealed "a growth of the esophagus at the cardia."

Fig. 3

Fig. 4

FIG. 3.—Barium enema showing relation of the hepatic flexure to the right diaphragm.
FIG. 4.—The colon after evacuation.

The x ray films well illustrate the high position of the proximal colon (anterior to the liver and directly under the right diaphragm) as well as cardiospasm and a distorted gas bubble due to malignancy at the cardia.

I quote in part from Howard Lilienthal's report as follows:

"First procedure, December 7, 1925: An incision about five inches long was made through the left rectus muscle with the umbilicus level at the middle of the line. The entire hand could be introduced and it was found that the right diaphragm was elevated high in the chest. This accounted for the x ray appearance of this region. All attempts to withdraw the

stomach failed because the organ appeared to be fixed firmly to the vault of the diaphragm. Rendered visible by the aid of strong retraction and drawing down the gastrocolic omentum, a nodular indurated mass the size of a large egg was felt posteriorly and was supposed to be carcinomatous mass probably of the cardia. A jejunostomy was performed.

"*Second procedure, December 24, 1925:* An attempt to make an esophagogastrostomy met with disappointment."

From the operation and histopathological findings, the fate of this patient is obvious.

An analysis of the case lends support to the contention that eventration of the right diaphragm was, in this instance, undoubtedly congenital, symptomless and irrelevant to the pathology of malignancy.

The Endocrine Glands of Rats in Parabiosis*

PROF. GIACOMO PIGHINI, M.D.
and MARIO DE PAOLI, M.D.
St. Maurizio, Italy

(*Concluded from page* 404)

It is nothing unexpected, therefore, if, in an experimental condition of mutual intoxication, like that which obtains in the humoral fusion of two beings of different constitution and trophism and is realized in maximum degree in parabiosis between a male and a female, although they may be of the same species, we encounter morbid reactions of the sort described. Indeed, this is a confirmation of the concept of a functional synergy between these different endocrine tissues.

To the acknowledged relations between adrenal gland and testicles and adrenal gland and ovaries a recent contributor, Leupold, has made an addition by showing that the cholesterin content of both varieties of tissue maintains a mutual and close relationship. For example, diphtheritic intoxication or the administration of thyroidin, which causes atrophy of the ovaries with accompanying diminution of cholesterin in the thecalutein cells, is attended by scarcity of lipoids in the adrenal cortices. Our studies bring a fresh contribution, therefore, to the doctrine of these interdependent functions.

As respects the thymus, the relation of its parenchymatous atrophy to the contemporary invasion of plasma cells deserves to be further investigated, as we propose doing in the course of our experiments. Regarding the cortical portion of the thymus, as already found in preceding studies (Pighini), as an active participant in the nuclein metabolism of the organism, and considering the intimate genetic relations sustained by nuclein metabolism with that of the lipophosphates, we see here a connection with the other tissues primarily in close association with that metabolism, like that which exists between the sex glands and the adrenal cortex. The occurrence of thymolysis, equivalent to a thymectomy, surely cannot be a matter of indifference to the organism, and since thymectomy in young animals is followed by changes in the endocrine system analogous to those we found in our rats, the hypothesis is inescapable that one of the principal causes of the alteration affecting other glands and organs resides in exactly those lesions of the thymus which are likely to appear first.

Recent studies of the thymus, the adrenals, and the sex glands in man and woman by Leupold and by Walter have confirmed these experimental inferences by Pighini by showing precisely how the thymus exercises a stimulative influence on the growth and nutrition of the adrenal glands, the testicle, and the ovary. The thymic changes in our parabiosed animals, the first to be manifested, cannot and do not exercise an influence on the nutrition of these other glands and on others similarly concerned in the general hormonic condition of the organism. Inasmuch as in parabiosis the process of reciprocal intoxication continues, even when the specific cells of the thymus have already been destroyed in large measure, it may be understood how variable must be the consequences of this experimental condition and those of true thymectomy.

We have already referred to the special lymphatic reactions in the spleen and liver, resembling those of protein intoxication, changes which, especially those of the Malpighian bodies, may be encountered only during the early stage following thymectomy, while later on the specific lymph cells of that organ incline toward atrophy. We will limit ourselves, then, to the consideration merely of certain points of agreement in the relation between the two conditions which especially attest the functional synergy between the thymus, the sex glands, and the adrenal cortex (to which might be added the anterior lobe of the pituitary gland, however slightly specific may appear the reaction of that gland).

Our studies bear, again, upon the discussion and interpretation of other phenomena and teachings connected with the physiopathology of sex. As a sample may be cited the idea of a gland of rejuvenation attributed by Steinach to the interstitial tissue of the testicle, a gland which will hypertrophy when the seminal vesicles are brought into a condition of degeneration (by ligating the deferent ducts), and will then exercise a sort of beneficent influence over the various internal tissues of the organism, so as to arrest and attenuate the involutive processes which conduce to old age. Now the toxic condition of parabiosis, which produces alterations at the outset in the seminal cells and favors hypertrophying on the part of the interstitial gland, does not in the later

*From the Lazzaro Spallanzani Scientific Laboratory of the Reggio Emilia Psychiatric Institute, directed by Prof. G. Pighini.

stages confer any advantage on the individuals joined together, who continue to advance to marasmus, while the very interstitial gland itself participates in the complete atrophy of the whole seminal gland.

The experimental conditions of parabiosis are different from those set by Steinach for the attainment of rejuvenation. However, the fact is not without significance that one may produce by other measures a hypertrophy of the testicular interstitial gland which will exert no beneficial effect on an organism hastening toward marasmus, while this same gland shares in the general toxic effects, advancing all the while toward atrophy. The testicular interstitial gland behaves in this respect as does that of the ovary. In regard to the concept of rejuvenation produced by hypertrophy of the interstitial gland from injury to the seminal ducts, we share the scepticism of many recent experimenters, among them Thorek. Nissen has published similar results as regards degenerative phenomena on the part of the sex glands in parabiosis, and similar phenomena brought about indirectly by the action of x rays; and cases are on record of genital infantilism produced by Frankel and Geller by irradiating the pituitary gland (with x rays), by Poos by irradiating some other part of the body, and by Pfeiffer by the photodynamic action of light in individual animals. The danger, however, arises that in such experiments, dealing with small animals, the action of the rays may be cathodic rather than luminous, and so may be predominantly brought to bear on the thymus, which is far more sensitive to such agents than any other internal organ; in which case the analogy of the pathological process between these instances and ours of parabiosis will follow more closely.

While we propose to make a further study of the effects of parabiosis in animals castrated and not castrated, on gravid and nongravid females, on animals previously rendered toxic or deprived of some gland of internal secretion, and on normal animals, we conclude from this first series of experiments that

1. Parabiosis between two white rats is always followed a few minutes after the operative intervention by the phenomena of tremor and of tonic clonic spasm, lasting for a varying period, and caused by a reciprocal intoxication in the central nervous system. That system, in rats in this condition, presents a congested appearance.

2. Parabiosis between white rats of different sex, when practised in animals which have already reached sexual maturity (above three or four months of age), renders them sterile and predisposed to disease in the internal organs with a clinical course which must lead to death in a marasmic condition after a period varying from a few days to some months.

3. The anatomopathological picture presented by the animals, more or less accentuated according to the phase in which the examination is made, is the following:

In the *thymus,* which is the first organ to show the effects of parabiosis anatomically (after one day), autolysis of the small round cells caused their disappearance and that of all the epithelial cells of the gland, Hassall's corpuscles included, with substitution in their stead of a rich proliferation of plasma cells.

In the *testicles* degeneration of the cells of the seminal series with formation from the first of masses of protoplasm enclosing accumulations of spermatocytes (and spermatids), the socalled giant cells, which continue developing until the disappearance or complete absorption of these elements, reducing the canaliculi to membrana propria and Sertoli cells: contemporary hypertrophy of the interstitial gland in the degenerative phase of the canaliculi, and hypothophy of the same after atrophy of the seminal element is established.

In the *ovaries* a change takes place in the follicles which brings them into a condition of atresia, and in the corpora lutea which depletes the lutein cells; they become infiltrated, at any rate, with plasma cells, while the internal vessels dilate. The thecalutein cells of the theca interna appear in the early stages to effect hypertrophy in an increasing degree on the part of the interstitial gland, which tends in the subsequent phase, on the contrary, to atrophy.

In the *adrenals* hypertrophy of the medulla with some chromicizing of the cells, and scarcity of lipoids —of phosphatids and cholesterin—in the cortex.

In the anterior lobe of the *pituitary gland* congestion and accumulation of large basophile cells.

In the *liver* new production of lymph nodes.

In the *spleen* hypertrophy of the Malpighian bodies.

In the *pancreas* hypertrophy of the islands of Langerhans.

4. Parabiosis between two males presents the same phenomena, but less pronounced. Among the internal organs the thymus is always altered in the first stage. In one instance the thyroid was found in a condition of parenchymatous struma.

5. The changes in the sex glands of heterosexual pairs are not effected by a direct antagonistic action of the sex hormones of the testicles and ovaries, but by the combined humoral state of each individual, which varies more the more frequently the animals differ in sex and the more advanced their age.

6. Male female pairs become sterile. But, in case they have undergone parabiosis at a very youthful age (less than two months) and are of the same litter, the male may display generative ability on reaching puberty, but after a little he too will lose that faculty.

Historical Medicine

Leonardo Da Vinci, Anatomist and Physiologist

LEOPOLD VACCARO, M.D.
Philadelphia, Pa.

Leonardo da Vinci is not generally ranked as a great physician, yet he was the founder of iconographic and physiological anatomy. One hundred years before William Harvey, as we are about to demonstrate, he had a clear conception of the circulation of the blood and gave an accurate description of it.

Morelli speaks of him as "perhaps the most richly gifted by Nature among all the sons of men." No greater painter ever lived, a preeminent mathematician, and mechanician, a man of an all embracing intellect, a seer who penetrated all his eye saw, a discoverer so inexhaustible that perhaps the world has never seen his like.

Leonardo seems to have interested himself in every branch of science, and everywhere through the mere penetrating power of his sight, coupled with the sagacity of his judgment, he appears to have forestalled science often by centuries.

LEONARDO DA VINCI
(From a drawing by himself)

William Hunter, who at the time of George III had seen the originals in the library of the King, wrote thus: "I expected to find anatomical designs adapted to a painter for the needs of his art; but I found to my great astonishment, that Leonardo had made a general and profound study. When I consider what pains he took for each part of the body, the superiority of his universal genius, his singular excellence for hydraulics and mechanics, the attention with which this man observed and studied the object which he had to design, I am fully persuaded that he was the best anatomist that lived at his time. Without doubt, he is the first who, to our knowledge, has introduced the practice of anatomical designs." Leonardo was the founder of illustrated anatomy.

He is also the founder of comparative anatomy. He has described the analogies that the organs of living animals present. He made comparative studies of man and monkey. His method by analogy leads us to acknowledge that all terrestrial animals are constructed on the same plan, that the same organs are found in all of them: the wings of the birds and the arms of man are similar members. In this respect he was the forerunner of the evolutionary theory of Charles Darwin.

Leonardo anticipated our whole modern natural science, that is to say, so far as this was possible, relying upon the eye alone and without the help of higher mathematics, which were not then known, of the new instruments, and of the mass of observations which had to be mastered by whole generations. For example, this man who died in 1519, who had been brought up in the strict belief of the Church, in a flat earth between Heaven and Hell, knew the system of Copernicus developed some thirty years later. How he gained this knowledge and in what connection it came to him, we know not. For his observations up to the present time, far from being all deciphered, and published, are for the most part aphoristic, often forming an unsolvable tangle of the most various thoughts, jotted down in the midst of, or under or across his sketches, or on the back of his sheets of drawings—thoughts often occurring to him in the midst of his paintings, which he evidently seized in a hurry, in order to use them elsewhere.

In Leonardo's writings we find no astronomical system. Yet on one sheet, under a number of mathematical calculations, we find written in unusually large letters, *il sole non si muove,* the sun does not move, not another word. Here we have clearly a sudden inspiration. But Leonardo is no visionary; he was throughout a positive intellect, never weary of seeking the *certezza delle scientie,* certainty of the sciences, by the strictly empirical and mathematical road. *Sperientia e' commune madre di tutte le scientie e arti,* experience is the common mother of all the arts and sciences, and *nissuna humana investigazione si po dimandare vera scientia, s'essa non passa le matematiche dimostrazioni,* no human investigation can lay claim to being true science, unless it can stand the test of mathematical demonstration. Experiment, therefore, and calculations must be brought into court as tests of the correctness of any assumed fact. In the same way on other sheets we find a succession of investigations and deductions all encircling this central idea of a stationary sun and an earth which is in motion.

Take, for instance, the important recognitions, *come la terra non e' mel mezzo del cerchio del sole, ne nel mezzo del mondo,* that the earth is not in the centre of the sun's orbit, not in the centre of the universe.

CIRCULATION OF THE BLOOD

If now we turn our attention from the movements of the constellation to the hidden movements of the body, we find that Leonardo with the help of a like magical power of vision suspected, or even had a clear idea of the circulation of the blood. Leonardo speaks of *il continuo corso che fa il sangue per le sue vene.* The continuous course of the blood racing through its veins, and over and above this that the blood flows back to the heart, *il sangue che torna indietro,* differs from that which, when the blood is driven out, systole,

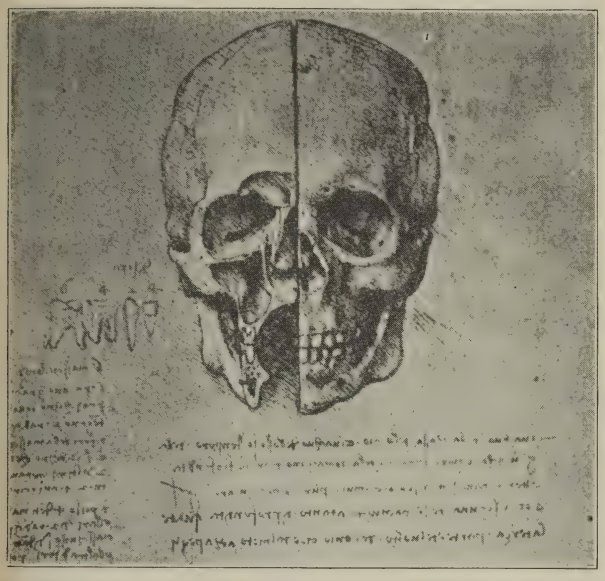

Fig. 3.—Study of a skull in section to show the bony cavities of the face.

closes the valves of the heart, *che riserra le porte del cuore.*

These words suffice to prove a deep insight into the mechanism of the circulation, which at that time was unsuspected and *not discovered* until a century later: for Leonardo knows that the blood runs an uninterrupted course through the veins, he knows that it proceeds from the heart, and finds its way back to the heart, and he makes a distinction between the venous blood and the arterial blood. And here we must bear in mind that the most important works of Leonardo in this connection as in others, are up to the present unpublished. They lie idle in the dust of libraries (2).

Gabriel Séalles (3) discussing the circulation of the blood as found in Leonardo's manuscript, Leic 2/ro J.P.R. II 849(a), says: "Leonardo compares the circulation of the blood to the movement of the water in the interior of the earth. He says, "The water goes from the rivers to the sea and from the sea to the rivers covering always the same circuit. Water is forced from the extreme bottom of the sea to the pinnacles of the mountains where, finding the veins blocked, returns by the shortest way to the low sea, again it rises by the ramified veins, then rebounds, coming or going from top to bottom, from side to side, and from front to back (H 101 V°). In this perpetual movement "it does like the blood of the animals which always moves departing from the sea of the heart and rises to the summit of the head; then if the veins are torn as one sees a vein broken on the neck, all the blood of the lower parts rises to the height of the broken vein."

M. Richer, who thoroughly and seriously studied Leonardo's manuscripts, writes: "From this passage it is evident that Leonardo not only suspected in a general way the circulation of the blood but that he had the clear and right conception of it."

William Harvey is generally credited with the discovery of the circulation of the blood. In 1628 he published at Amsterdam his *Excercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus.* It is not generally known, however, that in 1599 he went to Padua, then the most celebrated school of medicine in Europe, and attended lectures on anatomy, surgery and other medical branches.

He took the degree of M.D. and returned to England in 1602. He was to all intents and purposes an Italian physician and it does not require a stretch of imagination to see that he probably had access to Leonardo's manuscripts from which he might have drawn inspiration and ideas on which to elaborate his theory on the circulation of the blood.

LEONARDO THE ANATOMIST

As an anatomist (4) Leonardo applied to anatomy his constant method. He neglected the books of the Arabs and of the Greeks. To know the human body he observed. His object of study was the cadaver.

Anatomy occupied all his life. His first manuscript appeared in 1489 and his last in 1515. In the preface he enumerates the requirements one should have in analyzing the human body and how to arrive at conclusions. It is the language of a competent man who knows all the delicacies of his art.

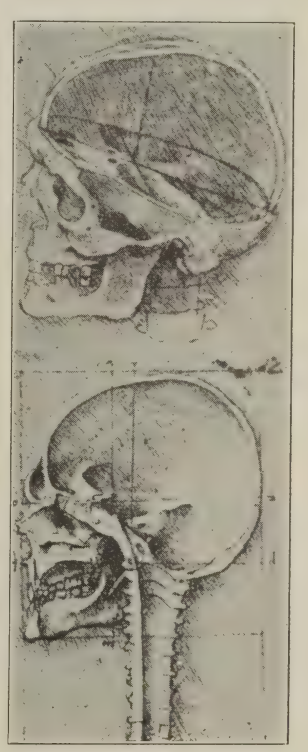

Fig. 4.—Studies of a skull in median section.

The plan of his treatise is greater. He described the uterus and studied the fetus. This is the beginning of embryology. He passes to the growth of the baby and the laws regulating his progress. Finally he arrives at a description of male and female adults. Different because of age and sex, all individuals of the species are made of the same elements, same tissues and same organs. He studied what is found in all the bones, muscles, and tendons, veins, and arteries, nerves, viscera. He studied the eye, the ear, and other organs of sense.

Mr. Jean-Paul Richter, who has consulted the Windsor manuscripts, gives in his bibliography some captions of the treatise on anatomy, such as: The Skull; The Skull and the Teeth; Measurements of Man; The Uterus; Its Veins and Nerves; The Geni-

tal Organs; The Muscles of the Leg; Muscles Which Move the Lips and Tongue; Trunk of All the Nerves; Lungs; Heart; Bloodvessels; Intestines; Stomach; Mesentery.

His last two books are a wonderful study of the

Fig. 1.—Studies of the deltoid muscle of the shoulder in various aspects.

heart—*l'impeto del sangue—la rivolutione del sangue mell' anteporta del corde,* demonstrating the circulation of the blood which was a century later described by William Harvey.

THE HEART

Leonardo made a profound study of the heart. "The heart," he says, "has the most powerful muscles. I have described the situation of the muscles which descend from the base to the apex and the situation of the muscles which originate in the apex and extend to the base." (G IV°) That he knew the structure of the heart thoroughly there is no question. Knox, the distinguished English anatomist, who studied Leonardo's original manuscripts, states that the drawings of the heart valves, especially the semilunar and aortic valves, imply a just idea of their function. Leonardo made a reflux of the blood from the ventricles into the auricles.

NERVOUS SYSTEM

On the nervous system Leonardo made some accurate observations. On the reflexes he says: "The nerves act by themselves without orders from other functions of the mind . . . one sees paralytics with their muscles, such as the head and hands, move without the permission of the mind." (W. An II 202 r°)

THE EYE

But the study of picturesque art and sciences lead Leonardo above all to reflect on the function of the eye. "The eye," he says, "has been defined by a number of authors, hitherto in a way entirely different from mine." On the nature of sight Leonardo speaks thus:

"I say that sight is exercised by all animals through the medium of light; and if against this any one should instance the sight of nocturnal animals, I would say that these in exactly the same way are subject to the same law of nature. For, as one may readily understand, the senses, when they receive the images of things, do not send forth from themselves any actual power; but on the contrary the air, which is between the object and the sense, serving as a medium, incorporates within itself the images of things, and by its own contact with the sense presents them to it, if the objects either by sound or smell project themselves to the eye or the nose by virtue of their incorporeal

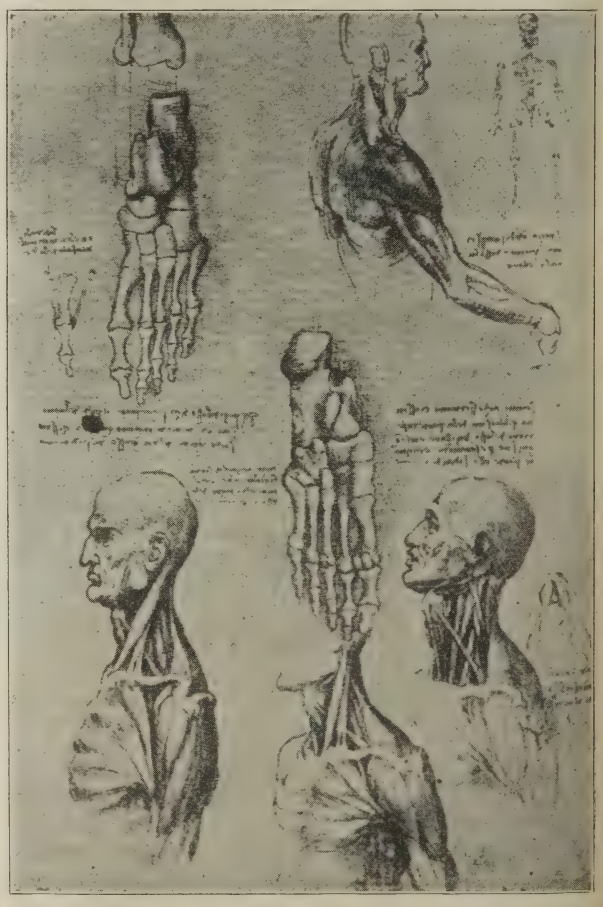

Fig. 2.—Studies of the anatomy of the neck and of the bones of the foot.

powers. Here the light is not necessary, nor is it made use of. The forms of objects do not enter into the air as images unless they are luminous; this being so, the eye cannot receive the same from that air which does not contain them, but only touches their

surface. If you wish to speak of the many animals which hunt their prey by night, I answer that when that small amount of light sufficient for them to see their way fails them, they avail themselves of their powers of hearing and smell which are not impeded by the darkness, and in which they are far in advance of man. If you watch a cat in the daytime leaping among a lot of pieces of crockery you will see that these will remain whole; but if it does the same by night it will break a considerable number. Night birds do not fly unless the moon is shining either full or in part, but their time of feeding is between the hour of sunset and the total darkness of the night. No substance can be comprehended without light and shade; light and shade are caused by light." (C. A. 90r. b.)

"Since the eye is the window of the soul, the latter is always in fear of being deprived of it, to such an extent that when anything moves in front of it which causes a man sudden fear, he does not use his hands to protect his heart, which supplies life to the head where dwells the lord of the senses, nor his hearing, nor sense of smell or taste; but immediately the affrighted sense, not contented with shutting the eyes and pressing their lids together with the utmost force, causes him to turn suddenly in the opposite direction; and not as yet feeling secure he covers them with the one hand and stretches out the other to form a screen against the object of his fear." (C. A. 119 v. a.)

Leonardo was the first man to discover the true nature of the eye. Before Cardan (1550) he had observed the dark chamber nature of the eye. The real discoverer, however, of the dark chamber, was another illustrious Italian who preceded him, L. Battista Alberti.

ON ARTERIOSCLEROSIS

Ambassador Caetani thus quotes Leonardo on arteriosclerosis:

"The death of old men, without fever, is caused by the veins which, going from the spleen to the liver, have their skin become so thick that they close and no longer give passage to the blood which nourishes them. The continued flow of blood in his veins causes the veins to become thick and callous so that at last they close and prevent the blood from flowing. An old man, a few hours before his death, told me that he had lived a hundred years and did not feel any bodily ailment other than weakness, and thus while sitting upon a bed in the hospital of Santa Maria Nuova at Florence, without any movement or sign of anything amiss he passed away from this life. And I made an autopsy in order to ascertain the cause of so peaceful a death, and found that it proceeded from weakness through failure of blood and of the artery that feeds the heart and the other lower members which I found to be very parched and shrunk and withered; and the result of this autopsy I wrote down very carefully and with great ease, for the body was devoid of either fat or moisture, and these form the chief hindrance to the knowledge of its parts. The other autopsy was on a child two years old, and here I found everything the contrary to what it was in the case of the old man."

(To be continued)

Contributors to the Science of Medicine

William Cullen

William Cullen, a contemporary of the Hunters and born not far from the village in which they were born, was as great a surgeon, a better teacher and quite as original a thinker as William Hunter, although he cannot be compared with John Hunter. Perhaps he is not so well known as the Hunters because he never left Scotland, but certainly he is one of the foremost of that brilliant band of Scotsmen who have added lustre to the name of Scotsman and to the medical and surgical professions.

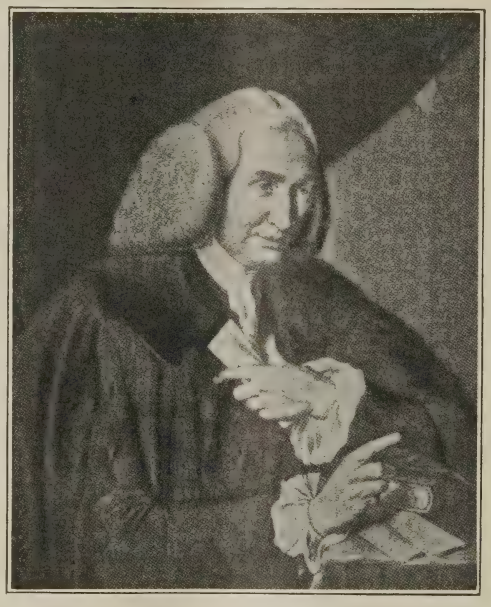
William Cullen was born in 1712, in Lanarkshire; his parents were in humble circumstances. After serving, as was the general custom of the times, an apprenticeship to a surgeon-apothecary in Glasgow, he became, as did another eminent Scotsman, Tobias Smollett, a surgeon or surgeon's mate to a merchant vessel. As a matter of fact Smollett served on a man of war, while Cullen was in the lowly position of surgeon to a merchant vessel, trading between London and the West Indies. However, his life at sea was short, he returned soon to his own district, and practised among the rustic inhabitants of the parish of Shotts, a region proverbial even in Scotland, for bleakness and poverty. There an accident favored Cullen and probably gave a color to his future fortune. The Duke of Argyle was staying in the neighborhood, and was anxious to do some chemical investigations, but some of the necessary apparatus were lacking. His host recollected young Cullen as a person likely to supply the deficiency. He was invited to dinner to meet the Duke and established himself in his good graces. Soon after this he removed to Hamilton where he made satisfactory headway, as at the age of twenty-seven he was appointed chief magistrate of the burgh. There he was a general practitioner, and was surrounded by apprentices in his pharmacy.

As said before, William Hunter was a native of the same part of the country and these kindred spirits entered into partnership. Their main ambition, then, was to procure the means wherewith to improve their medical education and position, and in order to further this object it was stipulated that each of them should be alternately allowed to study during the winter in a medical school while the other should continue to carry on the business in the country. Cullen took the first turn and passed the winter in Edinburgh. William Hunter chose London as his

place of study and the choice proved so propitious that he did not return. Thus ensued a premature dissolution of the partnership, as Cullen was not the man to throw obstacles in the way of his friend's advancement. They remained cordial friends and wrote frequently, although strange to say they never seem to have met again.

Soon after this another stroke of luck occurred to Cullen. The Duke of Hamilton was taken ill suddenly and sent for Cullen. He was attracted greatly by him and procured for him the post of lecturer on chemistry at the University of Glasgow. He shone in this position and became the idol of his pupils. He possessed a singular talent for arrangement which combined with his distinct enunciation, his vivacity of manner, and above all his thorough knowledge of his subject, rendered his lectures interesting in a degree hitherto unknown in Glasgow. His practice increased daily, and when a vacancy occurred in 1751, he was appointed by the King to a professorship of medicine.

In the meantime the authorities of the University of Edinburgh were very anxious to strengthen their medical teaching staff and their attention was directed to the rising fame of Cullen and when their professor of chemistry left this position Cullen was invited to take it. In 1756 he resigned all his offices and positions in Glasgow and came to the city which he helped to make the scene of his future triumphs. Chemistry had been neglected somewhat in Edinburgh and Cullen put forth his utmost powers to restore it to its rightful place. So successful was he in this attempt that more students attended the chemistry lectures than attended any other course, except that of anatomy.



WILLIAM CULLEN
(From Garrison's *History of Medicine*)

While professor of chemistry he delivered also during several years clinical lectures at the Edinburgh Infirmary. Alston, who was professor of materia medica, died in 1863, and Cullen succeeded him, and although in the middle of the chemistry course, persevered with his new subject to such good effect that while only eight or ten pupils had entered under Alston, more than one hundred enrolled under Cullen.

On the death of Dr. Whyte, Cullen rose yet another step and delivered lectures on the theory of medicine, ceding his chair of chemistry to Black, his former pupil. Next Rutherford, one of the grandfathers of Sir Walter Scott, disappeared from the chair of practical medicine. For this position Cullen and the great Dr. Gregory, known now chiefly as the deviser of Gregory's powders, were rival candidates. Gregory was perhaps the greatest medical therapeutist that Scotland ever had. It was arranged that these distinguished competitors should alternately lecture on the theory and practice of medicine. Their talents were dissimilar, and the students profited abundantly by the variety and emulation exhibited by these masters of their craft. Gregory was cut off suddenly in the prime of life and Cullen continued to occupy the practical professorship until a few months before his death.

As a lecturer he towered above the other Edinburgh professors of the medical department with the exception of Gregory. A few short notes sufficed to preserve a certain order with Cullen and an ease, a force, and a variety were thus imparted to his matter and his style which few have equalled. His particular illustrations were always fresh, apt, and suited to the occasion of the moment and his elocution was clear and bold. His arrangement was plain to the dullest capacity. He did not so much strive to imbue the student with particular details, as to present him with a general view of the whole subject, to show what had been already attained, to point out what remained to be discovered, and to place him on the road which seemed to conduct to a solution of the difficulties. A rapid outline was first drawn, in which the whole figure started boldly at once from the canvas, distinct in all its parts, and unmixed with any other object; presently he began to trace the picture anew, to strengthen the features, to sketch the distance, and to complete the whole in as perfect a manner as the state of his science would permit.

Cullen was the first to depart from the dictates of Boerhaave from which no appeal at that time had been made. He wrote several books. A small one on physiology, which had a considerable vogue in its day, was translated into French, German and Latin. His *First Lines of the Practice of Physic* appeared in 1784. This was translated into Latin, French, Italian and German. His *Nosology* is regarded as his best work. His *Materia Medica* was translated into many languages.

Cullen died in 1790 in the seventy-seventh year of his age. His appearance was striking and his countenance expressed the power within. He was a man of almost boundless nervous energy.

The Historical Exhibit at the Oporto School of Medicine.—The centenary of the foundation of the Medical School of Oporto was celebrated in 1925 by an historical exhibition which embraced the original royal decree authorizing the foundation of the school, many books, documents, etc., portraits of the distinguished professors and a notable collection of objects of historical interest from the excellent historical collection of Dr. Vittorino.

A sympathetic summary of the contents of this monograph with reproductions of the decrees, authorizing its foundation, is contributed to the fall number of the *Annals of Medical History* by Dr. Fielding H. Garrison.

Pyelographic Diagnosis of Renal Tumor

MEREDITH F. CAMPBELL, M.D.

New York

Exactly twenty years ago (1906) Voelcker and von Lichtenberg produced the first pyelogram. Since then improvement in all phases of this technic have led to its universal employment.

The pyelographic diagnosis of renal tumors is unquestionably the most interesting and probably the most difficult of urographic procedures. Kidney tumors are characteristically bizarre in their growth and the resulting pyelograms are so variable that discussion of the subject cannot be dogmatic. However, certain rather definite changes are seen in the pelvic outline in most of these cases.

The factors producing these variations from the normal outline are: 1, mechanical by, a, distortion of the pelvis by new growth; b, obstruction to urinary outflow — upper ureter involvement; 2, ulcerative, the result of infection plus sloughing of necrotic involved tissues.

Tumors of the kidney fall into four main classes: neoplasm, polycystic disease, solitary cysts, and inflammatory (abscesses). The latter two classes are rare, particularly renal carbuncle of sufficient size to be radiographically demonstrable.

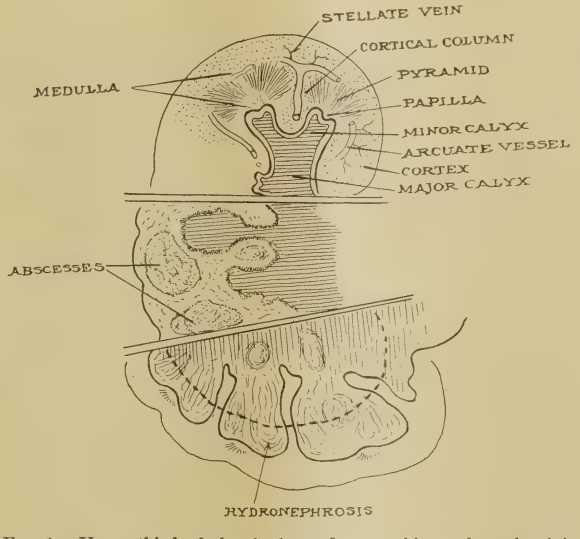

Fig. 1.—Upper third of sketch shows finer markings of renal pelvis. The projection of the papillary processes into the minor calyces produces the "cupping" seen in the normal pyelogram. With dilatation or infection of the pelvis, these markings are the first to disappear. Below are illustrated ulceration and hydronephrosis, conditions commonly associated with renal neoplasms.

Before proceeding to the consideration of the abnormal renal pelvis, let us consider briefly the normal. The finer details, the minor calyces and papillary processes are well shown in the upper third of Fig. 1. With most changes within the kidney involving pelvic outline, alteration or obliteration of these finer details occurs early. The kidney pelvis proper normally gives off two or three major calyces, most often three. These usually subdivide into two or more minor calyces. When two major calyces are present, subdivision into minor calyces is usually more marked, the greatest subdivision occurring at the lower calyx. Some of the more frequently observed types of normal renal pelvic outline are shown in Fig. 2.

The changes in the pelvic outline suggestive of new growth of the kidney are: 1, elongation of the calyces; 2, filling defect of the pelvis; 3, enlargement of the pelvis with or without evidence of alteration of pelvic capacity. All are phases of pelvic deformity. Displacement of the kidney and pelvic axis frequently accompanies tumor.

Elongation of the calyces is the mechanical result of tumor growth toward the periphery of the organ (Fig. 3). The involved calyx (usually one early, more later) is actually compressed by and drawn out with the tumor growth so that the later picture is that of a narrow streak. Rarely are the terminal calyces blunted; on the contrary, they merely fade out. These elongations are of variable length, the longest we have seen was 13.5 cm., an enormous hypernephroma. This is rare, however, as marked infection and ulceration usually intervene ere the growth reaches such size. Occasionally shortening and broadening of the calyces are seen, but this is not the rule with malignant growths. It is more commonly the accompaniment of polycystic disease.

As the tumor enlarges invasion toward the pelvis ensues. If infection and ulceration have not occurred,

the pelvis is compressed or flattened. In event of ulceration, variable degrees of flattening plus an irregular motheaten pelvis outline are seen. Changes in the true pelvis depend on extent of parenchyma involvement and on site of growth—a medullary growth causing earlier pelvic changes than a tumor

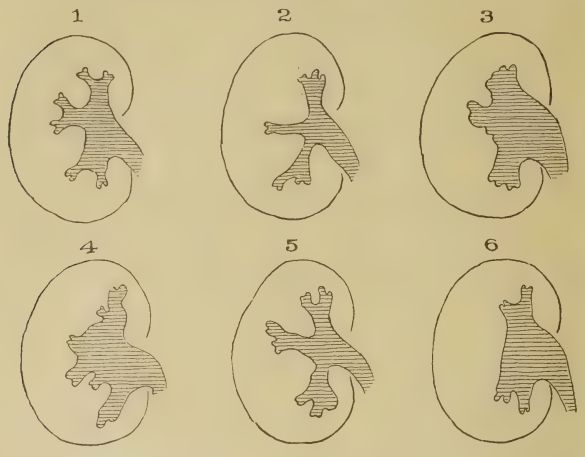

Fig. 2.—Normal renal pelvic outlines drawn from pyelograms. Although showing considerable variation in contour, it will be noted that the finer markings are well preserved in all.

of equal size in the cortex. Infection and ulceration, however, are important factors.

Filling defects of the pelvis occur chiefly with papillary growths of the pelvic wall, only late with parenchymatous tumors. Little change in the calyces

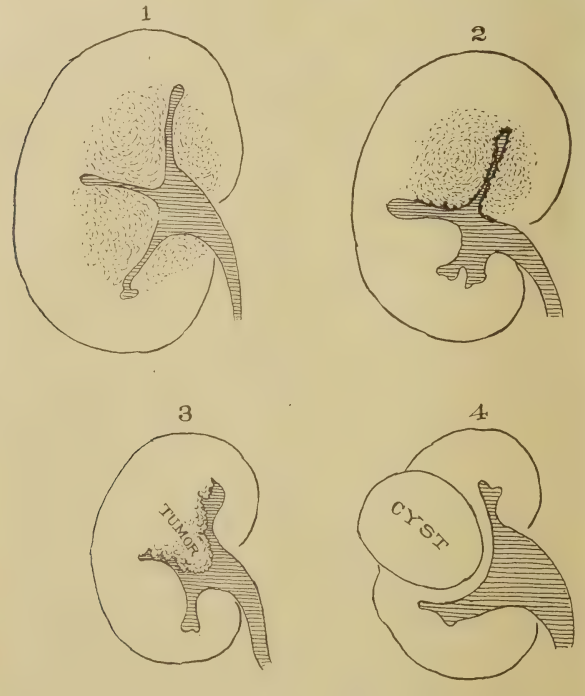

Fig. 4.—Drawn from pyelograms 1, hypernephroma 2, adenocarcinoma 3, papillary carcinoma 4, solitary cyst. Nephrectomy in all cases.

will be found with papillary tumors as a rule. There may be slight compression of the adjacent calyx. When papillary tumors reach such size as nearly to obstruct the true pelvis, intermittent blocking of the pelvic outlet with dilatation is frequent. Then outlines are particularly hazy.

Actual enlargement of the pelvis occurs late and may be the result of sloughing, obstruction, or mechanical retraction by the new growth. Sloughing occurs late in the life cycle of the tumor, is most often due to vascular thrombosis secondary to infection and may be extensive, giving a picture not unlike hydronephrosis in all details except for the marked irregularity and deformity so characteristic of tumor and not seen as a rule with hydronephrosis. It should be noted, moreover, that carcinoma causes sloughing relatively early and extensively, hypernephroma late and little. Ulceration is greatest with sarcoma.

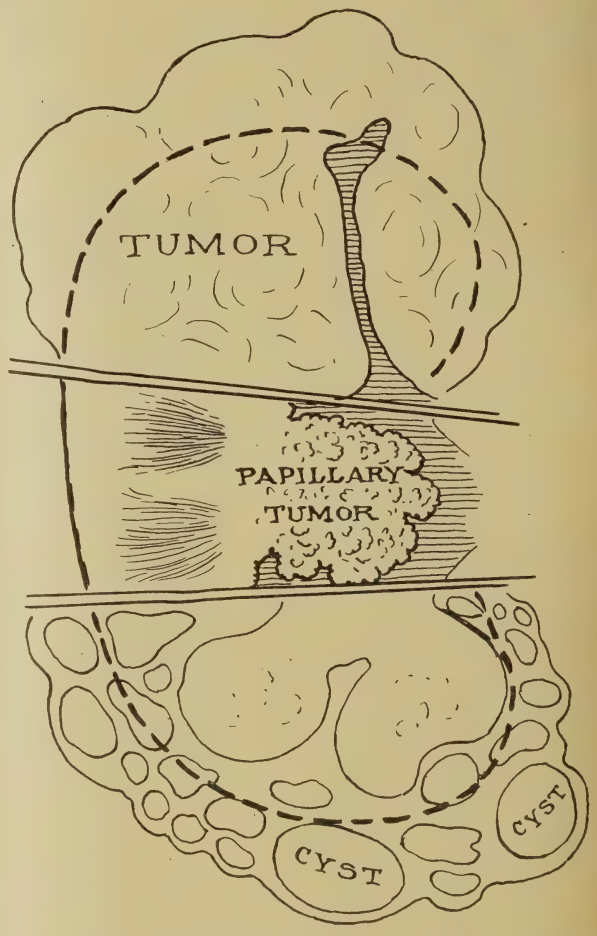

Fig. 3.—Pelvic deformity resulting from parenchymatous, papillary, and cystic tumors. Adjacent calyces are usually normal with papillary pelvic growths.

Obstruction at the pelvic outlet may be due to plugging by débris (slough, blood clot) or more often the actual involvement of the upper ureter by new growth. Here ureter changes are noteworthy. Inflammation causes a dilated ureter; new growth involvement constriction and obliteration.

This obstruction to pelvic drainage entails changes of dilatation in the pelvic outline. Those calyces not involved by tumor growth (if any) are dilated, the greater portion of the true pelvis presents an irregular appearance—motheaten, hazy—all in the presence of great deformity. To repeat, this deformity of pelvic outline is characteristic of all renal tumors malignant or benign, and differentiates neoplastic dilatation from that of simple hydronephrosis.

Of the kidney tumors, hypernephroma is by far the

most common. It usually begins in the upper pole of the organ, metastasizes early and freely, and may cause great suffering although cachexia appears late. Because this form of tumor shows necrosis late, extreme, regular deformity of the pelvis is found; the

Fig. 5.—Hypernephroma with globular streaking of the calyces. Nephrectomy.

streaking of the calyces may be pronounced. Clinically, a mass with hematuria and loin pain in the renal area, suggest tumor. When coupled with a pyelogram showing spider like calyces and great pelvic deformity, hypernephroma is the probable diagnosis.

Renal carcinoma is less frequently seen and is char-

acteristically a rapidly growing lesion showing early and extensive necrosis. The pyelogram is essentially one of great pelvic deformity with the irregular furred or motheaten outline characteristic of ulceration. As has been pointed out by others, the diagnostic triad—pain, hematuria and tumor—are not as marked as with hypernephroma. Cachexia is often extreme, appears relatively early and with a brief his-

tory of illness may be the outstanding clinical feature.

Papillary growths either benign or malignant are less frequently observed than either hypernephromata or carcinomata. Often hematuria is the only symptom. The pyelogram may show marked filling defect (occasionally complete obliteration of the true

pelvis) with or without pelvic changes secondary to ureter obstruction by the growth.

Other neoplasms, sarcoma, fibromata, etc., of the

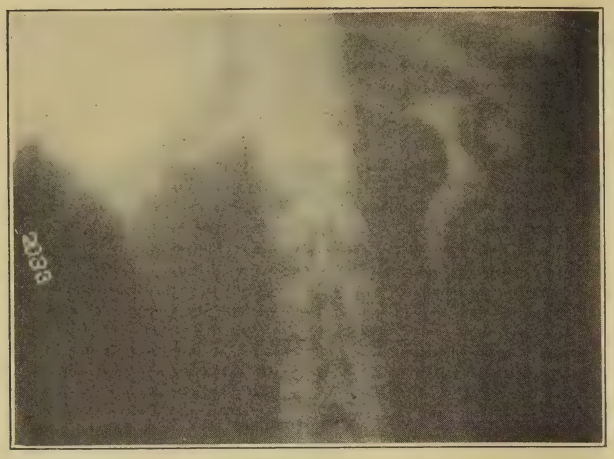

Fig. 9.—Adenocarcinoma involving lower pole of kidney with obliteration of the pelvic outline. There is some dilatation of the remaining pelvis and upper calyces.

kidney are rare. It is to be noted, however, that greatest pelvic deformity and destructive changes are caused by sarcoma.

POLYCYSTIC DISEASE

The pyelogram of renal polycystic disease is too variable to be described specifically. Changes are most inconstant. Relatively little elongation of the calyces is seen, rather are they shortened, broadened, or dilated with blunting of the minor calyces. This

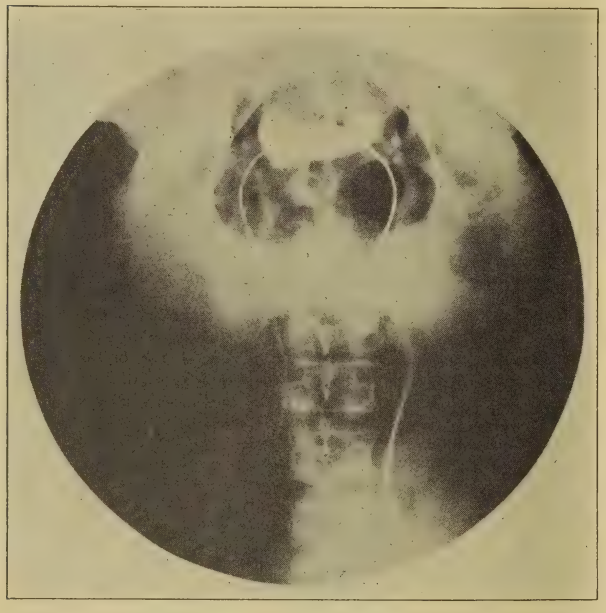

Fig. 10.—Papillary carcinoma with complete obliteration of renal pelvis. There is some dilatation of upper ureter, probably inflammatory.

dilatation may be round, oval, or crescentic and the appearance of round or crescentic calyces in the presence of a deformed or irregular true pelvis is suggestive of polycystic disease. Changes in the true pelvis are most inconstant. Polygonal dilatation is the rule. It has been asserted that pelvic contraction does not occur but we have recently examined three polycystic kidneys in which there was complete occlusion of the pelvis by cystic growth and compression. If infected, the pelvis shows a hazy outline.

Clinically the patient usually complains of loin pain; occasionally of a mass. Sometimes hematuria is noted; sometimes there are no symptoms until signs of renal failure appear. Many patients we have seen with this condition first noted the tumor themselves.

Fig. 11.—Nephrectomy specimen showing large intrapelvic growth with little parenchymal involvement. Pyelogram here showed filling defect of pelvis.

SOLITARY CYSTS AND ABSCESSES

Solitary cysts and renal abscesses, especially if adjacent to the pelvis, show a regular sharply defined

Fig. 12.—Polycystic kidney with grossly irregular pelvic outlines, some round, some concentric. Nephrectomy. Patient noted mass before seeking advice.

pelvic deformity—a flattening in the region of the tumor with compression of the adjacent calyces. We have, however, recently seen a pyelogram in a case of solitary renal cyst of the upper pole, the streaking

of the upper calyx and general pelvic contour of which was urographically undistinguished from that commonly observed with hypernephroma. Solitary cysts and renal carbuncles of sufficient size to be urographically demonstrable are rare.

Gross deformity and irregularity of the kidney pelvis may be suggested in a normal pelvis. This may result from a faulty pyelographic technic or mechanical difficulties, either causing incomplete filling of the pelvis. Chief of these mechanical difficulties may be mentioned, 1, stenosis of the ureter—either by inflammatory involvement as stricture—or from extraureteral pressure by tumor; 2, ureter dilatation to the extent that the radiopaque fluid is not retained in the pelvis. An obstructed catheter is passed occasionally.

Of other conditions causing pelvic deformity, perirenal tumor is most common. On the left side, enlarged spleen should be remembered; on the right side, a Riedl anomalous hepatic lobe may confuse. We observed aneurysm of the renal artery once giving symptoms and pyelogram suggestive of tumor. Cysts in the region of the kidney may compress this organ but the pyelographic picture in these cases is that of a kidney pelvis, which is possibly slightly rotated, displaced or flattened, but which shows a normal outline.

Pelvic changes secondary to renal calculus or the accompanying infection are usually explained by the röntgenographic demonstration of the offending stone. Hydronephrosis without tumor usually gives a pelvic outline which shows regularity, dilatation with shortening and rounding the calyces. Hydronephrosis with tumor most frequently shows elongated compressed calyces or the calyces may be absent; the true pelvis is dilated.

Filling defect may be simulated by blood clot or by an atrophic contracted pelvis secondary to an old inflammation. In the latter case, the pelvic outline is regular but smaller than usual.

On Kidney Diseases*

JOHN WILLIAM SHUMAN, M.D., F.A.C.P.
Los Angeles

One cannot think of renalopathies without considering the genitourinary system; kidneys, ureters, bladder, urethra and adnexa. Nephropathies cannot be studied without adequate knowledge of the cardiorenal vascular system. The kidneys are an important link in that chain. Remember the anatomical location of kidneys—for lumbago and sacroiliac disease have been crudely diagnosed as "kidney trouble."

Inflammation is the chief disease of the kidney. Nephritis may be active or passive. The active usually results from toxins, bacterial in origin. Nephritis may be classified as glomerular, parenchymatous or interstitial, according to the part affected. This is a bit unfair, for seldom is one diseased without the others being affected. Acute and chronic nephritis are fair terms. This terminology depends upon the time disease has involved the organs and the compensation which has taken place.

Passive congestion or cloudy swelling, so frequently viewed postagonal, is frequently present secondary to cardiac and hepatic failure. Both this and active congestion give urinary findings, such as albumin and casts, also an increase of blood urea, nitrogen, and creatin. Urinary obstruction (prostatic, etc.), causes renal passive congestion.

Fevers, especially scarlet, cause nephritis from mild to severe grades, because the kidneys eliminate much of the poisons. Focal infection (teeth, very often) is the most frequent underlying cause for the low grade nephritis which goes unrecognized until an acute exciting agent increases its intensity, for example, some severe acute illness, exposure, pregnancy, arsenic administration, and other conditions. Then are developed the signs of renal insufficiency; which may be, from scant urine, first degree pitting of shins, and foul breath—to anasarca, anuria, coma, collapse and perhaps death.

Study the eye grounds. Today with the electric ophthalmoscope no doctor should neglect examining the retinæ. Here the end capillaries can be seen and studied. This is of both diagnostic and prognostic value in cardiorenal vascular disease.

Clinically two types of kidney disease are seen—the dry and the wet. The latter (hydremic) is the anasarca type in which the tissues are water logged; there is a retention of salt and water, for the function of water excretion is impaired, the filter is clogged; and there is little evidence of cardiovascular changes. In the dry type (azotemia) there is lessened urea output (normal excretion thirty c. c. a day) and no edema; the nitrogenous bodies are retained and cardiovascular changes are well marked. However, there are mixed types of these two.

Prognoses referable to heart and kidney disease are more worth while today than ever. Prognosis in kidney disease depends upon:

1. A knowledge of the general clinical conditions, e. g., general weakness, loss of weight (or gain if hydremia), headache, vomiting, other gastrointestinal symptoms, convulsive seizures and other uremic symptoms, as well as various other conditions.

2. The physical condition of the cardiovascular system. Here worthy of mention is that high blood pressure is caused by overactivity of the sympathetic nervous system, stimulating the glands of internal secretion, causing a too high blood pressure, which injures the heart and bloodvessels. The kidney, being little more than a well constructed mass of bloodvessels, becomes greatly damaged. Later the bloodvessels and kidney help maintain a higher than normal blood pressure—further weakening the left heart.

*Fifth of six clinics held for Seniors of College of Medical Evangelists, Los Angeles, at Los Angeles General Hospital, April 15, 1926.

3. Biochemical tests. Some cases may be bordering on fatal termination without marked physical signs. So study these renal tests: a. General condition and symptoms and including the eyegrounds. b. The heart, and blood pressure. c. Blood urea; normal 20-40 mg. per 100 c. c. One test is not good—see if it is persistently high. It may be due to meat ingestion. Blood creatinin—elevation means serious impairment of elimination. Over five often means fatal prognosis. d. Urine; for not only albumin and casts but also for red and white blood cells. Increase in night urine means lack of kidney elasticity—works overtime at night to keep up elimination. With such a kidney the specific gravity is about constant.

If urea in blood and urine is both high, kidneys are functioning well. In the aged blood urea may be 50 mg. per 100 c. c. Prognosis is not hopeful if it is that high in the young and over seventy in the old. High blood pressure with advanced kidney changes indicates a hopeless prognosis.

The amount of albumin passed is no criterion of kidney efficiency. There is often much damage when there is but a trace. Albumin may mean globulin of blood, cathartics, pyuria. Also in adolescent children, following violent exercise. Do quantitative albumin tests, for if it decreases this is of good prognostic value. I put confidence in blood and urine urea tests and phenolsulphonephthalein. But all have fallacies.

Septic emboli do lodge in the end arteries of the kidney causing from minute to large abscesses. Some heal and are infarcts. Some form stone or calculus which may in time be dislodged into the pelvis and try to pass through ureter causing renal colic with its unmistakable agonizing, dull knife cutting like, radiating pain, hematuria, cold sweat, pallor, etc.—relieved by passing the stone or the administration of morphine.

A large kidney area may be due mainly to hydronephrosis, hypernephroma, perinephritic abscess or pyonephrosis. Tuberculosis is a frequent cause of the latter. In an adolescent, frequent micturition, increasingly so at night, and pus in the pan specimen speak for renal tuberculosis until it can be ruled out. It can only be ruled out by repeated microscopic examinations for the tubercle bacillus. Guineapig inoculation is helpful but slow.

Painless hematuria means malignancy until it can be ruled out. In both of these conditions the cystoscopic examination and segregation of urine is vastly important. Pyelography is often helpful.

In closing, cystitis is never primary—its cause may be from above, about, or from without.

The following illustrative case was reported by Dr. G. W. Harmon, an intern:

Case.—No. 242313, a sixty year old male Jew, peddler, admitted February 3, 1926, complaining of swelling of ankles, legs, hands and face, general weakness, frequent urination, shortness of breath and joint pain. Five years before he had had a similar attack.

A careful examination revealed focal infection of teeth and tonsils; heart enlarged to the left; anasarca, a moderate amount; proliferative arthritis of cervical, upper dorsal vertebræ and knee joints; urine contained albumin 29 to 168 per cent. and glandular casts plus 2, specific gravity 1012 to 17, few pus cells; prostate overfirm but not obstructing; blood pressure 178-104; internal hemorrhoids; liver, one finger below the costal margin; blood, hemoglobin 55 per cent., red blood cells 4,400,000, white blood cells 10,800; polymorphonuclears 60 per cent.; blood sugar 100.0, nonprotein nitrogen 30; preformed creatinin 1.5; uric acid 3.0.

Diagnosis: Senility with hypertensive cardiorenal vascular syndrome. Treatment: Rest and care.

2007 Wilshire Boulevard.

The Genesis, Occurrence and Management of Fulminating Uremias

ROLFE FLOYD, M.D.

New York

High nonprotein nitrogen figures not infrequently catch both the physician and the surgeon unawares and startle with their sinister significance.

Antecedent low readings in these cases, previous to an operation or to an illness without renal symptoms, make such reports the more astonishing because in chronic nephritis the rise of nonprotein nitrogen is apt to be a very gradual one.

These unpleasant surprises occur because the several causes of high blood nitrogen are not sufficiently kept in mind.

GENESIS

There are three principal ways in which considerable increases of nonprotein nitrogen occur in the blood stream; the first is physiological, the second and third are pathological.

1. When more protein is broken down in the body in twenty-four hours than usual, its waste products have to be carried from their sites of production to their only adequate channel of escape, that is, to the kidney. So the blood comes to be surcharged with nitrogen waste products until their surplus is disposed of. Such elevations of nonprotein nitrogen occur in pneumonia and after eating excessive amounts of protein food. They seldom reach one hundred mg. per one hundred c.c. of serum, and they recede as soon as the flood of extra nitrogen waste abates.

2. The second way that high nonprotein nitrogen occurs is so as to provide an abnormally high stimulus for an abnormally weak function. The presence of nitrogen waste bodies in the blood stream is the stimulus that makes the kidney draw them from the blood and the higher their percentage in the blood the faster the kidney excretes them. A percentage represented by about thirty mg. of nonprotein nitro-

gen is enough to make the normal kidneys excrete nitrogen waste at the same rate as it is poured into the blood stream and avoid its accumulation beyond the normal amount in the blood and other tissues. When this particular renal function weakens in disease, compensation occurs through increase of the nonprotein nitrogen in the blood, thus augmenting the stimulus enough to drive the weakening kidney to excrete as much nitrogen waste in twenty-four hours as it did when healthy. In this way a nitrogen balance is maintained, but at the expense of an increase of nitrogen waste in the body. All goes well till the nonprotein nitrogen reaches percentages where its unknown toxic components begin to poison the patient and then a vicious circle soon results in death.

3. The third way that high nonprotein nitrogen occurs is because of failure of the kidney's power to concentrate urea in the urine, or, what amounts to same thing, because of insufficient urine volumes. The normal human kidney can put from thirty-five to fifty grams of urea into one litre of urine, at the most, that is from three and five tenths per cent. to five per cent. Many normal kidneys cannot do so much and in disease this function often fails markedly, so that ten grams of urea, or less, per litre, becomes the maximum. One litre is an ordinary twenty-four hour volume and from ten to twenty grams an ordinary twenty-four hour production of urea, so the normal margin of safety is not great. Infections and operations depress this renal concentrating power, often reduce urine volume and regularly increase the production of nitrogen waste, so that volumes of half a litre, maximum concentrations around one per cent., and twenty-four hour urea productions of twenty grams are not at all unusual coincidences. The kidney can then only put five grams of urea into the half litre of urine and retention will progress at the rate of fifteen grams every twenty-four hours.

While the first and second kinds of nonprotein nitrogen elevation contribute to fulminating uremias, it is this third mode of production that is principally responsible for them. The shocking suddenness of these cases is all the more unexpected because the particular renal function whose failure causes them, i. e., concentrating power, is seldom adequately tested. The dye test and the Ambard or Van Slyke constants give direct information only about the power of the kidney to draw waste matter from the blood; they do not reveal the kidneys' ability to concentrate urea in the urine. It is not necessarily true that these two renal nitrogen functions, i. e., extraction from the blood and concentration in the urine, are both damaged in every renal failure, certainly not both to the same extent, so that testing one does not give sufficient information about the other.

On the other hand, the general reliance on specific gravity as a measure of the kidneys' ability to concentrate nitrogenous waste is far from justified. Persistently low and fixed gravities occurring when the fluid intake is low and when edema is not being absorbed, do mean weak concentrating power. But low gravities in single specimens or even in twenty-four hour collections when the fluid supply is not controlled have no such significance. These facts, though often forgotten, are generally recognized, but it is not so generally known that very fair gravities do not necessarily mean fair concentrating power. When the blood nonprotein nitrogen is well over one hundred mg. and the urine volume very scanty I have seen gravities of 1015 associated with less than half of one per cent. of urea in the urine (i. e., less than five gm. per litre). When information about concentrating power is desired, the specific gravity should always be controlled by testing the percentage of urea in the urine.

If the nonprotein nitrogen is high, above seventy mg., and the urine volume not over one litre, the urine content of urea reveals the maximum concentrating power. If the nonprotein nitrogen is not high there are two ways of discovering the maximum concentrating power; either by reducing the urine volume, or by raising the blood nitrogen. Volhard employs the first, Ambard and some American workers the second. As either plan takes time, such tests are very generally neglected.

CLINICAL OCCURRENCE

It is evident from what has just been said about their modes of production that such sudden elevations of nonprotein nitrogen will not be typical of any particular form of kidney trouble, but will be met in many different clinical conditions, where low urine volumes and weak concentrating power ocur together. If, at the same time, the nonprotein nitrogen is already elevated to drive a weak kidney or if coincident overproduction of nitrogen waste is taking place, the uremia will obviously be augmented by these factors.

Persistent vomiting, the anurias of active renal inflammation and of bichloride poisoning, the postoperative state, retention of urine in the bladder, and high intestinal obstructions are some of the more important conditions in which rapid increase of nonprotein nitrogen ought always to be watched for.

In persistent vomiting from whatever cause the urine should be measured. Attention is apt to be so focussed on the relief of the vomiting that the need of fluid is temporarily neglected and the possibility of a coincident weak renal concentrating power entirely omitted from consideration. I recall a case where the patient vomited for a week or ten days with gastric ulcer. A nonprotein nitrogen of one hundred and fifty mg. was then found. The kidneys showed no serious disease and the nonprotein nitrogen fell to fifty mg. in a few days on simple increase of urine volume.

In acute nephritis or acute exacerbations of chronic nephritis the urine may be reduced to a few ounces in twenty-four hours or it may even be completely suppressed and then the nonprotein nitrogen rises with startling rapidity. In such cases both the ability to draw urea from the blood and the ability to concentrate it in the urine are lessened, coincident with the failure of urine volume, so the rapid increase of nitrogen waste in the body is easy to understand. The nonprotein nitrogen in these cases, however, is generally closely watched because the symptoms direct attention to the kidneys.

In bichloride cases the anuria often results in rapidly progressive nitrogen retention which apparently causes or largely contributes to the frequent fatal termination. There are two circumstances,

however, that have confused the understanding of uremia in bichloride cases. The first is that the urine often begins to flow freely again by the end of a week or so, but the patient dies of uremia just the same, poisoned by waste already in the body, which the regenerating kidney cannot exhaust fast enough. The second is that many deaths from bichloride are not due to uremia or are not due to this alone and nonprotein nitrogen readings around one hundred mg. or less have often been found in fatal cases. It must be remembered that bichloride may kill in other ways than by causing uremia, notably by the colon lesions, so that we are altogether unwarranted in concluding that a patient with bichloride poisoning that has anuria and dies is necessarily killed by nitrogen retention.

The sudden uremias that occur after operation are perhaps the most important because they are the ones for which the most can be done. It has long been known that general anesthetics irritate the kidney, and recent work has shown that they depress the renal concentrating power. Fluid intake by mouth is often greatly reduced for a few days after operation and urine volumes of less than half a litre are not at all unusual. An extra amount of nitrogen waste is also apt to be produced in the operative field. These conditions not infrequently combine to rapidly raise the nonprotein nitrogen to high figures, and the danger is sometimes not realized, till the load of poison is too great to be successfully reduced. Fatalities of this kind have occurred often enough to make surgeons realize the danger of postoperative uremia and to guard against it by forcing fluids. This procedure is excellent and life saving but some surgeons do not yet quite understand just why the nonprotein nitrogen rises so fast. If renal concentrating power were tested before every major operation it would make the handling of power operative uremia more individual and more effective.

Sudden and excessive rises of nonprotein nitrogen associated with an equally sudden and excessive fall in the blood chloride have recently been observed in cases of high intestinal obstruction. While the genesis of these changes is still largely obscure, the vomiting and the blocking of the normal channel of water absorption must result in low urine volumes and add this factor to the others, that cause these large accumulations of nitrogen in the blood. Just how much uremia contributes to the symptoms and death in this condition in also not yet known.

When urine is produced by the kidneys but retained in too large amounts and too long in the bladder and ureters, on account of a mechanical block in the lower urinary passages, large amounts of nonprotein nitrogen may rapidly accumulate in the blood. Such uremias often prove fatal. They also constitute a major contraindication to the operation which alone can relieve the underlying condition. Their reduction requires an understanding of the way they are produced, but their genesis is not as simple as seems at first sight. Reduced urine volumes cannot alone be responsible, for urine is still produced by the kidneys, and in many cases a considerable volume dribbles out. Even when the urine is regularly drawn the nonprotein nitrogen may remain obstinately high. The renal concentrating power, while sometimes very low, is often not sufficiently reduced to alone cause the uremia, the urine containing ten or fifteen gm. of urea per litre. Back pressure of urine has been shown experimentally to diminish the secretion of water and urea by the kidney and doubtless is a factor in many of these cases, but, as just stated, some of these kidneys produce fair volumes of urine containing considerable quantities of urea, so back pressure cannot be the only cause. There is probably still another factor at work in these urine retention uremias. Many of the nitrogenous waste bodies are highly diffusible, urea especially so, so they are found in nearly equal concentrations throughout the body fluids and tissues. The membranes lining the urinary tract are the only ones in the body impermeable to nitrogen waste. It is quite conceivable that this special function may be deteriorated or suspended through distention, through inflammation, and through continuous contact with urine, so that resorption of nitrogen waste through the walls of the ureter and bladder may help to increase the nonprotein nitrogen in the blood.

In prostatic, vesical calculus, bladder tumor and urethral stricture conditions, then, the associated uremia is probably produced by varying combinations of four factors; viz., insufficient volume, failing concentrating power, back pressure and resorption.

MANAGEMENT

These fulminating uremic conditions, if untreated, regularly soon destroy life, but wise management not infrequently succeeds in preventing or even in reducing them. So the outlook in these cases is quite different from that in chronic nephritis with slowly but steadily rising nitrogen figures, where treatment can accomplish so little. Success in treatment depends on an accurate understanding of just how the uremia has been produced in each case and on knowing which renal function must be husbanded and which may be driven to compensatory activity.

There are two procedures that form part of the treatment in all these cases.

First, all nitrogen intake should be stopped, so that no addition from outside will be added to the overload of nitrogen waste already in the body. If, however, the treatment has to be prolonged beyond one or two weeks, minimum protein requirements should be supplied.

Second, the skin and the bowel, which constitute the accessory channels of nitrogen elimination, should be kept active. Sweating can be accomplished by the hot pack, the hot air or hot water bath, and by pilocarpine. The bowels must be kept open but I do not believe that the advantages of a constant diarrhea make up for its reduction of urine volume and for the weakness it induces.

In the uremias that occur after persistent vomiting or any cause that has so altered the fluid exchange as to produce continuously low urine volumes the chief indication is to increase the amount of urine, and the only way to accomplish this is to introduce more fluid into the body, either into the stomach, or into the veins, or under the skin, or into the rectum. Putting it in through a duodenal tube is an excellent plan if the condition of the stomach permits keeping the tube in place, for there is no channel of entry that can take care of as much fluid with as little disturbance as the wall of the small gut.

Whatever plans of fluid administration are followed the important thing to watch is the urine volume, for no matter how much fluid is given it can have no effect on the uremia unless large amounts of urine result. It is also important to determine the percentage of urea in the urine and its total twenty-four hour output for this gives information about the effect of the increasing urine volume on the uremia. Little is accomplished till an output of at least thirty gm. of urea is attained.

In guarding against postoperative uremia it is essential to obtain information about the kidneys before operation. The routine urine examination does not at all meet the requirements. While albumin, red cells and casts are danger signals that must not be disregarded, a normal urine gives no assurance whatever of normal renal functions.

The blood chemistry at least tells if the nonprotein nitrogen is up before operation and, when it is, precautions are obviously necessary, but it is just the cases where the preoperative nonprotein nitrogen is found within normal limits in which dangerous postoperative elevations are unsuspected until too late.

As already stated, the dye test and the Ambard or Van Slyke constants indicate the kidney's ability to draw urea from the blood but they do not directly reveal its ability to concentrate urea in the urine. These two renal functions often do vary together, so a poor response to the dye or Ambard test does suggest a weak concentrating power and vice versa, but it does not tell how weak the concentrating power is, which is what we most want to know.

If the nonprotein nitrogen is well over seventy mg. and the urine not over one litre in twenty-four hours, the percentage of urea found in urine may be taken as approximating the maximum concentration. If the nonprotein nitrogen is normal, fluid privation until the urine flows at a rate of less than half a litre in twenty-four hours with simultaneous increase of nitrogenous food will cause approximately maximum urea concentration. This result can usually be obtained within a period of thirty-six hours.

If the maximum concentrating power is under two per cent. every precaution must be taken to keep the urine volume up after the operation.

Even if the kidney can put over twenty gms. of urea in a litre, it must be remembered that this concentrating function weakens under strain and is also depressed by septic absorption and by anesthetics so that adequate urine volumes immediately following operation are the best insurance against postoperative uremia. It is not possible, so far as I know, to increase the renal concentrating power, but it is possible to prevent its depletion.

The cause of the uremic poisoning in these cases is not entirely clear. Loss of concentrating power evidently interferes with the elimination of urea but how does it interfere with the excretion of creatinin and other nitrogenous waste products, whose amounts never reach one per cent. in the urine, and why does it retard excretion of the toxic substances which are unknown but whose total amounts are so small in comparison to urea that a very few c.c. of urine should provide ample solvent for their elimination? I know no satisfactory explanation, but when urea is held back in the body through failing renal concentrating power or inadequate urine volume other nitrogenous bodies and the total nonprotein nitrogen collect in the blood in proportion to the urea, and uremic symptoms occur with nonprotein nitrogen figures similar to those encountered in other types of uremic poisoning.

In prostatic cases the high nonprotein nitrogen is often due to several factors, as already explained, and is therefore correspondingly difficult to deal with. Diminution of the concentrating power and of the power to excrete water fully and promptly, together with impaired ability to draw urea from the blood often coexist because of renal deterioration incident to the patient's age, and are all apt to be made worse by back pressure, while the nonprotein nitrogen may also be added to by resorption. It is imperative to raise the urine volume but the increase must be effectively evacuated or more back pressure and resorption will result. Frequent catheterization or the indwelling catheter, on the other hand, are likely to cause epididymitis and further depress renal function through fever and sepsis. The uremia, however, cannot be effectively reduced unless large amounts of urine are both formed and passed, and until the uremia is reduced, the operative risk is extremely great. After operation it is also vital to keep the urine volume up and this has to be done partly in the dark for the urine cannot then be readily measured. The best guide at this time is frequent determinations of the blood nonprotein nitrogen.

The most difficult of these fulminating uremias are those that occur when anuria or pronounced oliguria complicates acute inflammation of the kidneys. They are chiefly met in acute nephritis with scarlet, in bichloride poisoning and sometimes in severe exacerbations of a chronic nephritis. To make the urine flow is the primary indication, for the kidney cannot excrete urea or anything else unless it excretes water. How best to make the urine flow is a point on which very divergent views are held. Some clinicians force fluid intake to drive the kidney to excrete it, others believe that this is the worst thing that can be done and stop all the intake in order to give the inflamed and irritated kidneys as complete rest as possible.

Another point of difference concerns decapsulation. Volhard considers decapsulation imperative by the fourth day of anuria and reports success in over fifty per cent.; though I do not understand that he advocates the operation in bichloride cases.

In this whole group of fulminating uremias pessimism about the outcome and the effect of treatment is not warranted. The rapidity with which they accumulate justifies the hope that may be reduced. It is not infrequent to see nonprotein nitrogens up to two hundred mg. fall satisfactorily. Within the year a severe one occurred with an exacerbation of a chronic nephritis in a brain tumor case. The urine at first was bloody and contained less than half of one per cent. of urea. The volume averaged less than 350 c.c. in twenty-four hours for the first week and then rose but slowly. The nonprotein nitrogen rose from forty-two mg. at the onset to four hundred mg. at the end of ten days, remained at this level for a week and after this fell steadily until it reached practically normal figures at the end of three weeks more.

The slowly rising uremias of late chronic nephritis are almost impossible to reduce but in these sudden ones prompt treatment will often save life.

The Unilateroprevertebral Fused Kidney

With Report of a Case

ABRAHAM SAIKIN, M.D.
New York

Because of negative cystoscopic findings, recognition of fused kidneys without the aid of urography (a term introduced by Morrissey, indicating röntgenography of the urinary tract after it had been filled with an opaque solution) was quite impossible. The majority of these cases were discovered either at necropsy or on the operating table. It is only within the last decade that isolated cases began to appear in the literature, in which the diagnosis was made by urography.

FORMS OF FUSED KIDNEY

There are two forms of fusion of the kidney, namely: 1. The horseshoe kidney in which the fusion occurs either at the upper poles or at the lower poles and the kidneys are placed on each side of the vertebral column, more or less in the normal position.

2. The concrescent kidney of Gerard (1) is one in which the fusion is more or less complete and there is considerable asymmetry of renal tissue with the absence of horseshoe form. Stewart and Lodge (2) classify the concrescent kidney according to its position into three groups:

a. The unilateral fused kidney, in which the fusion takes place on one side of the vertebral column.

b. The prevertebral kidney; here the fusion takes place in front of the vertebral column.

c. The pelvic kidney, in which the fusion takes place in the pelvis.

Recently, Dourmashkin (3) collected seven cases of unilateral fused kidney in which diagnosis was made on living subjects by urography. Since then cases have been reported by Dunavant (4), La-Rose (5), Lowsley, Kingery and Clark (6), Caulk (7), Sexton (8), and Kretschmer (10).

The survey of urograms of the concrescent type of the fused kidney hitherto reported in the literature showed invariably that each one of them belonged to the unilateral fused type, that is, in every instance both pelves were situated on one side of the vertebral column; the ureter crossing the spinal column as it reached the opposite side.

The case which I have presented here is, I believe, the only one on record where the diagnosis of a prevertebral fused kidney was made by a pyelogram on a living subject.

FIG. 1.—A urogram showing the left pelvis and ureter of the fused kidney. Note that the kidney pelvis is situated in front of the vertebral column and that the calyces point upwards and inwards instead of outwards, which is normal. The left ureter emerges from the bladder in a normal fashion and runs towards the median line of the body.

CASE.—Y. T., woman, aged thirty-one, married, born in Russia, was referred to me by Dr. George Schwartz on January 18, 1926.

About February, 1924, patient consulted a surgeon complaining of pain in lower abdomen and sacral region. Patient was operated upon and a large single mass was felt in front of vertebral column, which was retroperitoneal and extended from the fourth dorsal vertebra to third sacral segment. A considerable portion of the mass could be traced to the right of the vertebral column and downwards towards the sacrum. This mass was thought to be a kidney, and as no previous cystoscopic examination of the urinary tract was done, it was left alone. An appendectomy was performed and the patient made an uneventful recovery.

The patient was not relieved by the operation and continued to complain of dizziness, headache, insomnia, constipation, and a sensation of fullness in the lower abdomen.

The patient was poorly nourished and somewhat anemic. The heart and lungs were negative. A healed right rectus scar was present. On abdominal palpation, a mass was distinctly felt just below the umbilicus in the median line of the body, extending towards the right iliac region for about three and a half inches to left of median line. The lower margin could be palpated just above the symphysis pubis. The entire mass appeared to be single, although at its upper margin a definite deep notch could be made out. The mass was soft in consistency and freely movable across the spinal column. The reflexes were normal. The blood pressure was 126 systolic and 78 diastolic. The blood count was 4,590,000 red blood cells, and 9,800 white blood cells with sixty-eight per cent. polymorphonuclear leucocytes. Hemoglobin was eighty per cent. Wassermann reaction was negative. A catheterized specimen of urine was clear, specific gravity 1024, no albumin, no sugar and no abnormal cellular constituents were found on microscopic examination.

Cystoscopic examination revealed a bladder of normal capacity. The mucosa was of normal lustre, and no abnormalities of any kind were noted. Both ureteral orifices were small, slitlike, and normally

situated. Renal catheters (No. 6 Charriere) of the olive tip variety were passed up to 21 cm. on right side and 13 cm. on left side. The segregated specimens of urine were obtained in a normal flow and on microscopic examination showed no abnormal cellular constituents. The urea concentration of the

Fig. 2.—The right pelvis and the ureter of the fused kidney. The pelvis is situated well to the right of the spinal column. All the calyces point inwards.

urine obtained from the right catheter was 1.4 per cent. and from the left catheter 1.1 per cent. phenolsulphonephthalein was injected intravenously and the dye appeared in the urine obtained from the right catheter at the end of three and a half minutes and in the urine obtained from the left catheter at the end of four minutes. The phthalein output from both sides was of a good concentration.

Seventeen c. c. of umbrenal (a solution of lithium iodide) was injected into left catheter until pain was felt by patient in the lower part of abdomen. The catheter was withdrawn and one and a half c. c. more of the opaque solution was then injected into the ureter.

A röntgen ray film was taken and developed while the patient was on the table with both catheters indwelling and the solution from the left catheter was allowed to drain off completely. When the unusual condition revealed itself, I decided, contrary to the rule of doing a bilateral pyelogram at the same sitting, to outline the right side. About the same amount of opaque solution was injected into the catheter and this time the patient began to complain of pain in lower abdomen and somewhat to the right of the median line, and two c. c. more of the solution was injected into the ureter while the catheter was being withdrawn.

SUMMARY AND CONCLUSION

The resulting urograms showed distinctly that we were dealing with a prevertebral type of a unilateral fused kidney. On superimposing both urograms the relation of both pelves to each other, and the relative position of the entire kidney mass could be well ascertained. The urogram showed that the left half of the kidney mass was situated in front of the spinal column, while the other half was situated to the right of the median line. That fusion actually existed, was proved by the previous operative findings, which disclosed a large single kidney mass. The latter could also be verified by abdominal palpation. As has been pointed out by Dourmashkin, the frequency with which kidney anomalies are overlooked and the patient is subjected to unnecessary operation, emphasizes the importance of a careful urological investigation in obscure abdominal conditions.

Fig. 3.—The composite urograms showing both pelves of the fused kidney. The branching calyces on both sides are seen to be separated by a very narrow strip of renal tissue. Note the low position of both pelves.

The Treatment of Enuresis*

ARTHUR I. BLAU, M.D.
New York

The care and treatment of enuresis in children has been and still is a source of considerable annoyance, both to the parents and to the medical profession. Not much satisfactory progress has been made in the therapeusis of this vexatious condition by any of the older and tried methods.

The affection from the viewpoint of its frequency and stubbornness is sufficiently important to warrant further investigation and study. In the clinic at the Lenox Hill Hospital I set in motion a series of clinical experiments to determine the effects of the various methods of treatment on this disturbance.

According to the textbooks a whole array of causes might be the responsible etiological factors. As a result of my study, however, I am tempted to say that the average case displays no tangible anomaly or infirmity, definitely causative in nature. It is true that in some cases we find a local or general condition which, by its reflex or constitutional action, may be the inducive factor in the vesicular disturbance, yet very few of the cases in which such local or general condition is found and removed or ameliorated, eventually are cured or improved. Evidently then one must look for a causative explanation in other channels.

Anatomically there seems to be a vesicular atony, particularly of the sphincter. What underlies this atony no one can say with any degree of certainty. My observations seem to point to a neurosis, the result of an undeveloped or unstable nervous system, and all the causative factors mentioned in the textbooks are contributory factors, keeping up and further undermining the neurotic element.

These forms of enuresis, which are by far the most common, may be designated essential enuresis, in contradistinction to those few in which the causative factor, whether congenital or acquired, can be definitely established and a cure or an amelioration effected by the removal or alleviation of that cause.

In the study under discussion a series of ninety cases were observed. Each child was submitted to a thorough physical examination, including urinalysis. A tabulation of the cases follows:

AGE	*Cases*
4 to 6	38
7 to 9	28
10 plus years	24
SEXES	
Male	41
Female	49
TYPE OF ENURESIS	
Nocturnal	69
Diurnal	2
Nocturnal and diurnal	19
PHYSICAL FINDINGS	
Enlarged tonsils and adenoids	16

Caries	8
Malnutrition	6
Phimosis	2
Bronchitis	1
URINARY FINDINGS	
Bacteria	5
Ammonium phosphate	3
Uric acid	2
Calcium oxalate	2
Albumin faint trace	2

*From the First Pediatric Clinic, Lenox Hill Hospital and Dispensary.

Among the most common affections were enlarged or diseased tonsils and adenoids, with anemia a close second. Phimosis was present in two cases. Removal of the tonsils and adenoids had no effect upon the urinary status, nor had circumcision any effect where phimosis was present. General measures for the correction of the anemia and malnutrition were favorable only insofar as the general conditions were concerned.

The hygienic and dietetic treatment, as well as the general and specific measures commonly used in the treatment of enuresis, were the same in all cases. Most of the cases in the series were treated for months with the usual drugs thought to exert a beneficial effect. Thus strychnine, ergot, belladonna, and a host of other drugs were used, without, however, any material benefit. Only few of the cases responded to these medications. Fifteen of the cases were then put on atropine exclusively. The results of these, however, were no better.

In the balance of the cases, seventy-five in number, pituitary extract and pituitrin were used. Pituitary extract was administered orally in all of these cases, one tenth to one quarter grain, at gradually increasing doses, three times a day. In fifty-four of the cases the oral administration was augmented by the hypodermic use of pituitrin, one half c. c. A series of three injections was generally given, at intervals of three days.

TABULATION OF RESULTS

OF THOSE INJECTED

Improved	21
Cured	16
Unimproved	7
Not observed	10

The period in which these observations were made extended from May 5, 1924, to January 5, 1926. Results were judged after a period of treatment of from three to twelve months.

The duration of enuresis before treatment was begun was as follows:

	Cases
Less than one year	10
Less than two years	28
Over two years	37

From this it is seen that in fifty per cent. of the cases the enuresis was more than two years in duration before treatment began.

The best results were obtained in those who received both the injections and the oral administration of the extract. Particularly favorable results were obtained in those who received the entire series of three injections. Thirty-seven cases out of a total of fifty-four injected were either improved or cured, almost seventy-five per cent. Had we been able to give all the children the full series of three injections, the percentage of cures and improvements would have been considerably higher.

Furthermore, ten of the injected cases never returned for subsequent observation. On the face of the results obtained in cases fully followed up, it is no exaggeration to say that some of these also were improved or possibly cured, still further swelling the percentage of favorably results. Even those who were only treated with pituitary extract orally, almost thirty-five per cent. showed either an improvement or a cure.

Other investigators also report favorable results obtained from the use of pituitrin in the treatment of enuresis. Bonacorsi (1) reports recovery of eight out of twelve children and great improvement in three. She used a series of injections. Our results are sufficiently encouraging to warrant a more widespread use of this remedy in the treatment of this stubborn malady.

CONCLUSIONS

1. Basically vesicular atony is responsible for enuresis.

2. The majority of cases of enuresis fall in the category called essential enuresis, which is probably a neurosis, primarily responsible for the bladder atony.

3. The use of pituitrin in the treatment of enuresis has proven more favorable than any other therapeutic measure. Almost seventy-five per cent. of our cases were either improved or cured from its use.

4. Further clinical experimentation with pituitrin in the treatment of enuresis is desirable.

Enuresis with Report of Two Interesting Cases*

WILLIAM J. EZICKSON, M.D.

Philadelphia

It is not my desire in this paper to go into details regarding the general subject of enuresis. You have all met this problem in your daily practice and as a result of various kinds of treatment, and often in spite of treatment, the children graduated from the bed and pants wetting class. However, I know it is quite a frequent occurrence that in spite of all treatment and the advice to mothers concerning proper management of children in this respect, this troublesome condition still continues. Since most children sooner or later become continent, both mothers and physicians have accepted the situation as a necessary evil. The mother has become lax in her training and the physician rather lax in carefully searching for a cause. You may ask, why thoroughly study every case of enuresis, most children grow out of it and if you did examine them thoroughly, seldom could you find any definite causative factor. True enough, but all don't improve. And that brings us to the group of cases who will not respond to the ordinary treatment and care. It is my opinion that any child who has incontinence during the waking hours after the third year and during sleep after the fourth year should have a very thorough physical examination. If this were done more often, fewer children would pass from one physician to another for months and years and finally some serious pathological condition may be found. In the meanwhile the child has been drugged, dieted and punished with and without the whip and the mother has become discouraged and distressed; and it has all been in vain because the real cause has been overlooked.

You must bear in mind the possibility of congenital deformities and abnormalities.

Peripheral causes acting through reflex irritation are not infrequent. Thus incontinence may be due to vaginitis, to an adherent clitoris, or to phimosis. It may be due to thread worms in the rectum, to constipation, cystitis, pyelitis or hyperacidity of the urine. The diet may play a part. Large amounts of highly nitrogenous food and a diet rich in sugar may lead to urinary changes sufficient to cause the trouble. Enlarged tonsils and adenoids have been found as causes.

*Read before the South East Branch of the Philadelphia County Medical Society, April 1, 1926.

I wish to emphasize the great importance of frequent examinations of the urine, when searching for the cause.

I will now cite two cases, which I feel will concretely illustrate the necessity of careful and complete study of the incontinent child:

CASE HISTORIES

Case I.—H. E., aged six. Referred by Dr. Rose Rubin. First seen February 5, 1925. Chief complaint urinary frequency and enuresis nocturnal and diurnal for past two years. Whooping cough six months ago. Measles two years ago. Tonsillectomy had been performed in November, 1924.

The boy was poorly developed, but had no evident abnormalities of heart or lungs. Abdomen seemed rather distended. Urinalysis showed trace of albumin loaded with pus. Urine was exceedingly cloudy. Blood count was normal. X ray examination of kidneys and bladder was negative. Was treated for three months, giving large doses of sodium citrate and various urinary antiseptics but symptoms still continued and repeated urine examinations still showed it extremely cloudy and loaded with pus. I then believed that the boy had some serious pathology in the bladder or the kidneys, suspecting the possibility of patulous ureteral orifices or congenital obstruction at the urethrovesical orifice, or a pyelonephritis. I, therefore, had the child brought to the Northern Liberties Hospital. I secured a catheterized specimen of urine which was sent to the laboratory for culture.

With the catheter in the bladder several ounces of ten per cent. neosilvol were injected through the catheter into the bladder and x ray pictures taken both in recumbent posture and with extreme elevation of hips. The plates proved negative except for some dilatation of bladder. Culture from urine revealed a pure growth of colon bacillus, from which an autogenous vaccine was made.

The boy was given this vaccine every other day in ascending doses. In about two weeks the urine started to clear and the frequency became much less, diurnal enuresis ceased but the bed wetting at night still continued. At the end of one month, the urine became entirely clear, there was no urinary frequency and he wet the bed only once or twice weekly.

At the end of two months the enuresis ceased entirely, the urine was absolutely clear and repeated microscopic examinations revealed no pus cells. The vaccine was discontinued. The boy gained eight pounds in weight and has continued to gain. He has been under my observation off and on for the past six months and none of the symptoms have returned. No other treatment was given while he was receiving the vaccine.

Case II.—R. B., aged eight and a half. Referred by Dr. Louis Kirshner. May 16, 1925. Chief complaint: Enuresis with occasional distress over bladder. Headaches. Eczema at age of four months. Croup at nine months. Measles at one year. Tonsils and adenoids removed at age of two. At four years of age was struck by automobile and sustained an internal linear fracture of skull. Had progressive paralysis of right side of face. This paralysis remained stationary for about one year and then gradually improved and now there is only slight impairment. December, 1924, operated on for acute catarrhal appendicitis. No complications.

Enuresis present more or less since babyhood, but had become markedly worse during the past two years, and now with little control during the day also. Further questioning elicited the following symptoms: Frequency with passing of small quantities of urine, very restless and irritable. Appetite poor. Slept poorly. Progress in school poor. Memory poor. No history of convulsions.

The boy was of fairly good development. Head was rather large with bulging forehead, slight weakness of muscles of right side of face and some ptosis of right lid. Heart, lungs, abdomen, extremities and genitalia negative. Examination of spinal column revealed a very marked depression about the region of the sacrum. Blood Wassermann: negative. Blood count: reds, whites and differential normal. Urine was negative. X ray examination made by Dr. Mulford Fisher. X ray of kidneys, ureters and bladder proved negative. X ray of vertebræ showed the presence of a spinal bifida occulta involving the upper two segments of the sacrum. The family moved to Detroit, therefore nothing was done here.

Delbet and Leri (1), 1923, report a case of enuresis in a young man aged twenty-three. Nothing was found to account for the condition except a spina bifida occulta. They operated, resecting the band of fibrocartilaginous tissue which compressed the dural sac of the nerve of the cauda equina. Enuresis ceased immediately. Since then the authors have done several similar operations.

F. O. Pybus (2) in the *Lancet* in 1921 mentions enuresis as a symptom in some of his cases of spina bifida.

J. S. Leopold (3) in 1920 reported a case of spina bifida occulta with incontinence of urine and feces in a girl age six. She was operated on and the incontinence disappeared after operation.

Beck (4), Von Recklinghausen (5), Borst (6), Hesse (7), Von Finck (8) have written rather fully on this subject.

CONCLUSIONS

In conclusion, I wish to impress the extreme necessity of careful searching for a definite cause in all cases of enuresis which do not respond to the ordinary methods of treatment.

Some Untoward Effects of the Arsphenamines

C. W. BIRNIE, M.D.
Sumter, S. C.

Sufficient time has elapsed since Ehrlich's wonderful discovery to appraise accurately the arsphenamines in the treatment of syphilis. At first heralded as an absolute cure, and even now thought to be by a large part of the laity and many physicians, we know that this view is fallacious and that by itself it does not cure syphilis, but that mercury and iodide of potash in conjunction with arsphenamine is still our sheet anchor in treatment. Besides, bismuth has assumed an important place in some cases. The administration of arsphenamine is almost routine in every physician's office, so that it will not be amiss to look over some of the ill effects and accidents that have occurred from its use.

1. Accidents due to faulty technic.
2. Accidents due to the drug itself.
3. Accidents due to the disease itself.

ACCIDENTS DUE TO FAULTY TECHNIC

The most common accident due to faulty technic is the infiltration of the tissue with the drug, producing a cellulitis. This happens either because the vein has been missed altogether or the needle has gone through the vein. The damage varies from the formation of a nodule to actual necrosis of the tissue, either of which is extremely painful and causes much inconvenience for a considerable time.

Phlebitis and septic infection are due to lack of proper sterilization of the instruments, the patient or the physician himself.

H. J. Nichols, of the United States Army, mentions thrombosis as a complication reported to the Surgeon General's office. A possible source would be the injection of unfiltered solution which may contain some of the undissolved drug, fine particles of glass or some other foreign body.

Syncope is encountered quite frequently and in most cases is caused by either too rapid administration or too great concentration of the drug. For the injection of a ten c. c. solution, and for intravenous injection we should never use a less amount, at least five minutes should be required.

Nausea and vomiting are usually due to the administration of the drug too soon after eating. The best results are always obtained with an empty stomach.

ACCIDENTS DUE TO THE DRUG

Accidents due to the drug itself are in a large measure unavoidable, for there is no way of knowing which patient has an idiosyncrasy to arsenic or how it will manifest itself. These ill effects have been exhibited as skin eruptions, ranging from a simple erythema to a severe dermatitis, purpura or jaundice. Chills and fever and diarrhea have been noted. Fritz, in the *Archives of Dermatology* of Berlin, mentions cases of epilepsy, nephritis, myelitis and anemia of the brain.

ACCIDENTS DUE TO DISEASE

The accidents due to the disease itself are principally those which affect the nervous system. In spite of Nichols's logical theory to account for these nervous relapses there is still doubt as to whether the Bell's palsies, the hemiplegias, the epilepsies are due to the drug or to the disease. Nichols explains it as follows: "Let us imagine a case in the secondary stage with wide dissemination of spirochetæ throughout the body. Certain strains invade the nervous system as well as other parts of the body. . . . The only symptoms may be a headache, except in those cases in which a paralysis may occur. If such a case is given mercury, especially over a long period, the spirochetæ are gradually repressed and reduced in numbers and produce no further nervous symptoms in most cases. The same result may occur without any treatment on account of stimulation of the natural defenses of the body. In a few cases, however, either because the drug does not reach the spirochetæ or because new and resistant strains develop, the organisms multiply again and produce definite nervous symptoms, especially in the tertiary period.

On the other hand, if this patient is given one or two doses of salvarsan and no other treatment, the bulk of the spirochetæ in the body are suddenly destroyed and the symptoms and the Wassermann reaction disappear. All of the spirochetæ are not killed, however, some survive, either because they are inaccessible or resistant, and in a short time they begin to multiply, and they meet no resistance such as is afforded by mercury or the resistance of the body which has not been stimulated continuously by the parasites. As a consequence the organisms multiply locally to an enormous extent and produce a sudden explosive relapse. The effect of the relapse is most evident in the most sensitive tissue, that is, nervous tissue, and here we see such results as deafness, blindness, hemiplegias, etc."

The theory stated above accounts admirably for nervous relapses which occur some time after treatment has been stopped, but does it account in a satisfactory manner for cases where treatment has been recent or actually going on?

A few cases from my own experience will illustrate some of the accidents mentioned above.

CASE I.—A. W., colored male, about thirty years of age, complained of general pains. History of sore on penis a few months previous. Inguinal and cervical glands enlarged. No Wassermann was made. Was given an injection of neosalvarsan. About an hour after treatment patient started for home, ten miles from town. On the way was seized with a violent chill, nausea, vomiting and diarrhea. The nausea and diarrhea cleared up within two days but the chills and fever continued for a week.

CASE II.—J. B., colored male, aged twenty-seven, laborer from Clarendon County. Gave a definite history of syphilis. No Wassermann because of history and his wife had shown a four plus reaction. An injection of neosalvarsan was given with no bad results. A week later another. Two days after the second treatment he had a chill followed by high temperature.

Three days later he had a fine rash over the entire body and an intense jaundice had developed. He was given large doses of magnesium sulphate, and recovered in about three weeks.

Case III.—S. K., Greek male, aged fifty. Restaurateur. He came with a small sore on the penis not definitely outlined. No enlarged glands. Wassermann negative. Under local treatment the lesion on penis healed. Four weeks later came back with enlarged inguinal and cervical glands. Wassermann again made and it was now four plus. Was given four injections of neosalvarsan with no bad results except a slight chill and fever after each dose which cleared up in two days. He was then given eight intramuscular injections of mercury. Wassermann was again made, this time by two laboratories, one was four plus, the other negative. An injection of sulpharsphenamine was then given. The chill and fever were more severe than before. At the end of a week another injection was made. In three days the patient came with a well marked purpura on the buttocks which rapidly invaded nearly the whole body, including the mucous membranes of the nose and mouth, the latter organs to such an extent that profuse and almost uncontrollable hemorrhages occurred. On advice of Dr. M. Weinberg, eight intravenous injections of 0.6 gram of sodium thiosulphate, dissolved in ten c. c. of distilled water, were given; the first five every day, then every other day. In two weeks the skin began to clear and in a month all signs had disappeared. Since then I have given him twelve intramuscular injections of bismuth and the Wassermann is negative.

Case IV.—S. B., colored, farmer, aged forty-five. He complained of rheumatic pains and requested an injection of salvarsan. His blood had been sent off a few weeks previously by another physician and there was a positive Wassermann. A neosalvarsan injection was given and in eight days he returned—all of his pains having left him. Another injection was given him. In five days he returned with a typical Bell's palsy. This has gradually cleared up under ascending doses of potassium iodide.

Case V.—R. J., colored male, chauffeur, aged twenty. He came with a lesion on his penis, enlarged inguinal glands and a rash over his whole body. He was given an injection of neosalvarsan. In ten days he returned with a Bell's palsy, but the syphilitic symptoms had disappeared. He refused further treatment but the paralysis slowly left him without any treatment.

Case VI.—L. R., colored female, aged nineteen. Domestic. She presented an inflammatory condition of both eyes and enlarged cervical and inguinal glands. Wassermann, four plus. She was given an injection of sulphsalvarsan. In a week she returned apparently much better. She did not resume treatment. A few days later there developed a Bell's palsy which is improving under further arsenical treatments.

Case VII.—S. B., colored male, automechanic, aged twenty-two. He had clinical symptoms of syphilis but Wassermann was negative. After he had received two injections of neosalvarsan Bell's palsy developed. Further treatment with arsphenamine, also with mercury and iodide, produced no results. He went North and resumed treatment. While there his blood showed four plus. On his return gave him four injections of neosalvarsan and twelve of mercury. His blood is now negative, but some signs of the palsy persist, especially about his eye.

Case VIII.—E. W., colored male, carpenter, aged forty-five. No sore or rash. Vague pains over the whole body. Wassermann, three plus. I did not see him again for some months. I was called to his home one night and found him with a complete hemiplegia. Two days before he had been given an intravenous injection of one of the arsphenamines by another physician. He died the following day.

Some of these accidents can be avoided by a proper examination and a little precaution.

In persons suffering with cardiorenal affections, with a systolic blood pressure of 200 or over, with nonluetic liver troubles, with marked degeneration of the nervous system, with great disturbance of the optic nerve, salvarsan should be given very cautiously, if at all.

TECHNIC AND PRECAUTIONS

Observance of the following technic and precautions will often save some very unpleasant results.

1. Examine the heart, urine and blood pressure.
2. Never give arsphenamine if patient has been taking arsenic by the mouth recently. If patient shows any idiosyncrasy, discontinue its use and give the other drugs. A negative Wassermann reaction does not always mean that the persons has no syphilis, but a positive reaction is almost sure proof that he has. When in doubt give a small provocative injection and take the blood again.
3. Be sure of your sterilization. Approach this in the same way that you would a major operation.
4. Do not administer within three or four hours after eating and never while the patient is under the influence of alcohol.
5. Solution should always be freshly prepared and filtered before using. Always use sterile distilled water.
6. Be sure that you are in the vein. This can be easily told by the flow of blood. If the injection gives pain stop at once and find another vein.
7. Inject slowly and always test needle to see if it is clear, also expel all air from syringe.
8. If patient shows a bad reaction stop at once.
9. Never allow a patient to leave your office for at least half an hour after treatment. Instruct him to go to bed on reaching home.
10. The diet should be watched for a few days.

I am greatly indebted to Dr. M. Weinberg for his kindly criticism and valuable suggestions in the preparation of this paper.

Practical Therapeutics

Some Newer Developments in Endocrine Therapy

H. H. RUBIN, M.D.
New York

Until a few years ago, the atom was regarded as the smallest particle of matter known. More recently, however, it has been discovered that the atom is a complicated structure, consisting of a positively charged central body—the nucleus—surrounded by negatively charged electrons (2). Some of these electrons revolve around the nucleus at a speed of several billion times a second. The simplest atom is hydrogen, which has one positive nucleus and one negative electron. The heaviest and most complicated atom is that of uranium, which has 238 positive and 146 negative charges in the nucleus which of itself is surrounded by 92 negative charges. Thus the negative charge always balances the positive charge.

All matter varies according to the atomic makeup, the number and arrangement of the electrons. The tremendous speed at which the electrons travel around the nucleus causes a terrific energy to be exerted, which holds the atoms together, or else the entire universe would rapidly disintegrate.

Some atoms, however, are known to be unstable, i. e., they disintegrate at regular intervals, ejecting some of the positive and negative electrons. With these ejections, which are like violent explosions, waves of great velocity are set in motion, which are electromagnetic in character. The elements whose atoms disrupt in such fashion are called radioactive and there are more than forty of these elements known.

Radium is the outstanding radioactive element, having a high degree of activity and a comparatively long life—about two thousand years. There are several rays ejected from radium which are well known and measurable by instruments of precision. The principal rays are the alpha, beta and gamma, the alpha being a positive helium atomic nucleus, the beta an electron, and the gamma an electromagnetic wave traveling with a velocity of light 186,000 miles a second (4). The penetrability of alpha and beta rays is little compared with the gamma ray, which "can penetrate a foot of solid lead" (3). All electromagnetic waves are measured by their length. The Hertzian or radio waves are several hundred feet long, while the gamma ray is about one tenth of an Angstrom unit (one one hundred millionth of a centimetre) and its frequency is twenty times higher than that of the x ray (1).

The physical and chemical effects of radium rays are: 1, penetration of opaque matter; 2, production of heat; 3, emission of light; 4, phosphorescence and fluorescence; 5, photographic action; and 6, ionization. The penetration of opaque matter and ionization are physical qualities which concern us mostly here as we assume these to be responsible for the marked stimulating effects on the human cell.

According to Simpson (4), the alpha rays are absorbed by .089 mm. of epithelial tissue and are therefore of little therapeutic value. The hardest beta rays lose about ninety-four per cent. of their energy after passing through one cm. of epithelial tissue. The gamma rays, however, are capable of penetrating 20.4 cm. of water, 18.3 cm. of blood serum, or 7.6 cm. of muscular tissue (Giraud).

The radium rays are said to be capable of ionization which is explained as follows: The rays, in passing through the air, strike an atom and separate one or more of its electrical charges from it. The newly separated electrical unit or electron is then called an ion. Due to the impact of the rays, these ions travel at a great speed and soon fill the air, which, when well charged with these ions, becomes an electrical field and the air is then said to be ionized or electrified. The same ionization can be effected in fluids, such as comprise seventy-five per cent. of the human protoplasm (6). Moreover, such ionization is constantly going on within the living body. That this phenomenon is essential to life has been proved by Professor Zwaardemaker (11) by his remarkable experiment described as follows: A frog's heart was kept active by artificial circulation. Upon extraction of the potassium from the circulating medium, the heart stopped beating. The heart was then radiated with a few milligrams of radium for about a half hour, after which it started beating again.

Potassium and radium are both radioactive and when the potassium was removed from the circulating medium, the heart failed to receive the normal ionizing influence and therefore ceased functioning; but when this ionizing influence was substituted by means of radium, heart action was restored. Even in plant life, the effects of ionization have been demonstrated. Everyone has observed in a field of corn that stalks growing in the shady places were dwarfed, compared with those which grew in the presence of the ionizing effects of sunshine. Some time ago Professor Rusby doubled the growth of plants by artificial root radiation.

Dr. W. J. Morton (9), in discussing the physiological effects of radium emanation, states: "The primary effects of the emanation treatment are largely due to the ionization produced. . . . It is, therefore, fundamentally electrical. The activity of the various ferments of the body is increased. Chemical reactions become more active. This means an increase in the rapidity of tissue oxidation, in short an increase in the sum total of all the chemical exchanges known as metabolism, together with a corresponding elimination of the waste products." . . .

Van Noorden says that "radioactive substances give us a method of distributing the carriers of electrical energy in the interior of the body and there engage the fluids, the protoplasm and the cell nuclei in the immediate bombardment of electrical atom explosions."

Saubermann (7), Seide (8), and Colwell and Ross (10) all agree that radium, in certain doses, has a

decided beneficial effect on the human organism. There are other theories as to the exact *modus operandi* of radioactive substances in the human body which are being investigated. However, the ionization theory, as described above, seems to be the logical one, since it is fundamentally an electrical theory. The more we grope into the realm of physiology, the more we are drawn into the field of physics.

Crile, in his monumental work (5) states: "Irritability, assimilation, reproduction, the universal characteristics of living matter as distinguished from the nonliving, are electrical phenomena. . . . The specific characteristic which differentiates the living animal organism from the nonliving materials of which it is composed would appear to be the frequency and force of these electric discharges rather than its static structure. . . ."

The extremely short wave length of the gamma ray and the very high frequency and marked penetrability render it convenient and adaptable for the treatment of the deeper structures of the body—such as the endocrines—by local application.

The endocrine glands are readily ionizable on account of their colloidal structure. The amount of radium employed for this purpose is about twenty milligrams contained in a round plaque about four inches in diameter. The plaque is so constructed and screened as to withhold the emergence of any of the alpha and most of the beta rays. We thus obtain the filtered gamma rays, minus the alpha and beta rays. The plaque is then applied over the region of the various endocrines according to their surface anatomy, at a skin distance of about one inch. The exposure time ranges from five to ten minutes over each gland affected, such time varying with the degree of subfunctioning of that gland. In our experience, covering a period of about three years and the number of patients totaling close to fifteen hundred, we have found in most cases a five minute exposure over each gland repeated daily or thrice weekly for a period of approximately two months was sufficient to restore the normal functioning of that gland.

The alleviation of the symptomatology was accompanied by a rise in the previously lowered basal metabolism and blood pressure, demonstrating that both subjectively and objectively the patient had definitely improved. There has also been noted a marked degree of permanency in the improved status of these patients. A great number have been followed up for a period of more than two years without evincing any sign of a relapse. No untoward effects have been discovered; occasionally radiation of the pancreas would produce mild radiation sickness, slight nausea and headache, which subsided within a day or so and did not recur when treatment was resumed.

The advantages of this method over ordinary organotherapy are manifold. It is a more effective method and is fraught with less empiricism. In cases where the oral administration of gland extracts produces gastric disturbance or cannot be tolerated for other reasons, and in psychoneurotic patients who are possessed of a phobia for hypodermic or intravenous injections, the gamma ray method of endocrine therapy is especially indicated.

Space does not permit us to cite individual cases, but the remarkable results obtained by this method in various disturbances complicated with or ascribable to dysfunctioning of the endocrine glands, which manifest themselves in those symptom groups recognized by the endocrinologist and internist as definite endocrine dyscrasias, urge us to invite the medical profession to further exploration of this fascinating new field of endocrine therapy.

The Use of a Respiratory Stimulant in Surgery*

O. HUEBLER, M.D.
Vienna, Austria

Numerous reliable therapeutic substances, with prolonged effect, are available for stimulating the diminished frequency of respiration. I have obtained decidedly remarkable results by using coramine in cases of respiratory difficulty, and am in position to confirm the observations of Franz Uhlmann to the effect that coramine not only increases the respiratory rate but also renders the respiration deeper.

Preceding every major operation the patient receives 0.02 gram of morphine, causing an artificial lowering of the respiratory frequency; the simultaneous administration of one ampule of coramine antagonizes the depressive action of morphine upon the respiratory rate. Wherever this method was employed, the general anesthesia was normally uneventful, and the respiration was quiet, regular and deep.

We have further availed ourselves of the advantage offered by this remarkable action of coramine, and shortly after the operation, during the stage of awakening, when symptoms of asphyxia frequently appear, have resorted to repeated hypodermic injections of coramine. This treatment resulted in the prompt relief of the symptoms, rendering the respiration quiet, deep, and regular.

It is well known that postoperative nausea and vomiting may be influenced by quiet respiration. The

*From the Section of Orthopedic Surgery of the Wilhelmina Hospital, Vienna.

increased depth of the respiration resulting from the administration of coramine may have been the reason why postoperative pneumonia, a complication not infrequent after cholecystectomy, was never observed in our cases.

In a series of cases, I was able to confirm the observations of Thannhauser and Fritzel that coramine elevates the blood pressure in collapse. These were instances in which collapse occurred in consequence of severe hemorrhage incident to the operation. Prompt administration of coramine intravenously changed the picture immediately. The pulse, which was hardly perceptible at first, within two to five minutes became full and rhythmic; the general pallor disappeared and the patient, breathing deeply, conveyed the impression of being asleep. When the intravenous administration is used, the action is immediate and persists from a half hour up to several hours; when the injection of coramine is repeated, it again promptly produces a similar effect. No undesirable effects due to overdosing were noted, even though in one case as many as five ampules were given within an hour.

I wish to caution against the use of coramine in those cases where the lowering of the blood pressure is caused by blood escaping from the vessels, as for instance when the hemorrhage is from an ulcer of the stomach or from wounds. In these cases the hemorrhage frequently ceases in consequence of the diminished blood pressure, and the lowering of the blood pressure may have a lifesaving effect. When the blood pressure is too rapidly increased following the use of coramine, the hemorrhage, which has already stopped, may commence again. I have encountered such an experience with a patient suffering from hemorrhage from a gastric ulcer and with another patient who had been wounded in the lungs. In these cases preference should be given to analeptics that possess slower action.

CONCLUSIONS

Coramine is a remarkable analeptic, which on account of its prompt and reliable effect is almost indispensable in medical practice. It is especially useful in surgery, for the treatment of difficulties of the respiratory centre, following general anesthesia. Because of its simultaneous action on the diminished blood pressure, it affords the surgeon opportunity to relieve promptly conditions of collapse arising during and after operation. Coramine permits of exact doses and has a more prolonged effect than camphor preparations. The facts that injection is painless and that abscess formation has never been observed, contribute to its advantages over camphor, the dose of which is uncertain and its effect slower to appear. Furthermore, the convenience of oral administration may be particularly valuable when treatment needs to be continued over a protracted period of time.

Ephedrin in Asthma.—William S. Thomas (*American Journal of the Medical Sciences,* May, 1926) presents an analysis of the effects produced in twenty patients and concludes:

Ephedrin, administered by mouth to a series of twenty patients, suffering from asthma, has given relief to all but three and is an important substitute for epinephrin as a palliative remedy. In certain respects and in certain cases the newer drug is to be preferred. In certain asthmatic patients for whom no means of permanent relief has been found, the drug has been used in regularly continued dosage with the result of keeping them asthma free during the period of its administration.

Its advantages over epinephrin include: 1, The fact that it is effectual when given by mouth; 2, the fact that its effects are more prolonged than those of epinephrin; 3, the absence, in most cases, of tremor and palpitation as by effects of doses sufficient to relieve bronchospasm.

Among its disadvantages, as compared with epinephrin, are: 1, Its occasional failure to relieve asthmatic symptoms where the older drug does relieve; 2, by effects, occasionally met with, which then render its use impracticable even though it relieve the bronchospasm (it is possible that these ill effects may be nullified by proper means); 3, when given by mouth, its effects are, of course, less rapidly produced than are those of epinephrin given hypodermically. Ephedrin, however, may also be given subcutaneously; 4, delay in obtaining ephedrin is unavoidable at present.

A field for the use of ephedrin appears to lie in its employment as often as is necessary to prevent the occurrence of paroxysms in asthmatic patients that are awaiting the completion of skin tests, courses of vaccine administration, rhinological treatment, radiotherapy or other methods from which more permanent benefit is hoped. When effectual, its use in these preventative doses has been more satisfactory than the treatment of paroxysms by injections of epinephrin.

Whether the long continued administration of this drug to particular patients will prove to be harmful to them or not, is not known at present.

Experimental and Clinical Investigation of Mercurochrome.—A. T. Todd (*Lancet,* November 14, 1925) is convinced that mercurochrome is a powerful antiseptic of low toxicity, rapid and deep penetrability, and causes little irritation. It does not precipitate albumins. If protected from light it is stable for long periods in normal saline solution. Its antiseptic properties are augmented by acidity; they are diminished by increased density of solvent and are likely to be less apparent in heavy infections. Various strains of an organism show differences in susceptibility. At acidities near to normality its antiseptic properties are relatively feeble and it is unlikely to be of value in general infections.

Value of Irradiated Cholesterol in the Treatment of Rickets.—Leonard G. Parsons (*British Medical Journal,* March 20, 1926) reports a case of severe rickets which was under treatment for the greater part of one year. For five months the child received codliver oil but with only slight improvement; during the last three months of the year it was given three per cent. irradiated cholesterol in linseed oil, with the result that the rickets was cured. Whilst it clearly is impossible to generalize from one case, the results obtained suggest that this method of treatment is well worth a trial either alone or in combination with codliver oil, in cases which do not respond quickly to codliver oil alone. It is not an expensive method of treatment.

Editorial Articles

EXERCISE AND HEALTH

It is an axiom beyond peradventure that to have and to maintain good health exercise is essential. It is also an indisputable fact that when the man settles down to business, and the woman to domestic life or business, exercise is largely neglected, with physical and mental deterioration as a result. The individual is likely to become obese and lethargic with a dulling of the senses and the will to work, or the exercise taken is unsuitable, incomplete and insufficient, and overeating becomes a habit, followed by its natural corollary of a poisoning of the system by its retained waste products.

The true object of exercise is to maintain physical fitness, and with it that mental alertness necessary to carry on business or any sedentary work with success, after the passage of the active years of life. In short, to keep physically fit in middle and later life. How best to accomplish this end is told in a book written by F. A. Hornibrook, published recently by Cassell and Co., Ltd., London. Mr. Hornibrook points out that even when exercise is taken during middle life, it fails to attain the most beneficial results because it does not go far enough and is not followed up by reasonable selfdiscipline.

The neglect of the abdominal muscles is the point upon which the author insists chiefly, and to this neglect he attributes much of the ill health which, as Dr. Leonard Williams remarks caustically in an introduction to the book, "pursues this ignorantly self-indulgent generation." Reeducation of the abdominal muscles, according to the gospel of health preached by Mr. Hornibrook, is a long step in the direction of recovering and securing good health, and moreover, it is open to all middleaged men, who suffer from no serious organic disease, and who have abused their bodily functions carelessly and unwittingly.

The main argument in the thesis set forth is that civilized people ignore or are unaware of the value of abdominal exercises as practised by primitive people in their native dances. Attention is drawn to the fact that it is not by guesswork that the abdominal and pelvic regions are made the pivot of the native dance exercise. The native belief is, that if the lower half of the trunk is properly exercised and developed, the rest of the muscles can be and are thrown into action simultaneously. It is maintained that the native dance exercises are based on the sanitation of the bowels as the primary principle of health. All natives believe that the health of the body is in the bowels; that when the bowels are clean, the whole body is clean; and that when the bowels are unclean, the whole body is full of uncleanness and that bowel cleanliness is dependent on really efficient evacuation.

It may be said that medical men and the public generally in civilized life hold that the sanitation of the bowels is essential to good health, but they use different methods to accomplish this object. They are likely to depend on the usual forms of exercise in vogue and on artificial means, or when their opportunities for exercise are difficult, or practically unattainable, to rely wholly on artificial means. Abdominal exercises, the technic and details of which are explained fully in this book, and diet, are the methods which the author teaches to ward off disease and to maintain physical fitness in middle and later life.

THE HARRISON NARCOTIC LAW

When the Federal (Harrison) Narcotic Act was enacted there was considerably less information about the illicit use of narcotic drugs by habitues than there is today. With the knowledge at that time available the federal regulation was consistent and its enactment desirable. The opinion formerly prevailed throughout the country that narcotic drug habituation was in the main incident to careless prescribing by physicians and loose pharmaceutical issuance. Today we know such is not the case.

The experiences of some half a hundred special narcotic clinics in some twenty-eight states; the enforcement—or partial enforcement—of the Harrison Law, together with several state and many municipal statutes relating to this topic, have furnished data on which we, today, may with safety consider regulation of narcotics from an entirely different angle. From medical supervision to police control.

A rather short police experience in New York city with many thousands of cases of narcotic habituation in nonmedical individuals has demonstrated a more than practical method of consideration: in fact, if it were practical efficiently to enforce the present laws they would not meet the situation; with an amendment, such as we have in mind, along police control lines, it might not only curtail smuggling considerably but actually prevent considerable of this material from falling into the hands of those who use it for sinister enterprises.

Opium in its resinous or raw state is not used to any extent by the modern drug addict: he prefers, and uses, the drug in its refined state, which clearly demonstrates that methods of issuance of morphine

must be revised if we are to make any progress in this control. America is one of the largest users of this drug (opium) and our per capita of imports is excessive for medical and scientific purposes. For instance, in 1922, the importation into the United States was about seven grains of opium—in morphine the equivalent of seven eighths of a grain—per individual.

Some one has made the statement that about half of the narcotics used by addicts are smuggled. We then ask, from where and to whom? Thus there is a rumrow or bootlegger who supplies the underworld with drugs—which naturally must be obtained illicitly and distributed illegally.

The beverage bootlegger has his source in stills, smuggling, diversion, and needs all means of transportation to move his wet goods from source of supply to point of distribution for the users, but the narcotic bootlegger does not have to have such bulky accessories. He cannot, or does not, refine the raw produce. The legitimate refiner of opium is his source, not the grower of opium. These goods are easily gathered in either by himself or his agents, not only here but in all places where opium is refined into morphine—England, France, Germany, Switzerland and this country—and communication between these are frequent. Personal messenger service, or disguised shipments, do the trick. Here is indicated a needed amendment to meet this issue. It must be made impossible for refined opium to fall into the hands of the illicit dealer or bootlegger. Some say it cannot be done. It is possible but it may be difficult.

Heroin, a derivative of morphine, has met its Waterloo in a recent national prohibitory amendment, but it is not practical so radically to consider morphine, which is an essential of medical practice in very numerous instances.

Physicians have been under great hardship to prescribe narcotics in quantities or for any length of time to patients in need of such relief from pain. Today the Harrison Narcotic Act unnecessarily burdens the practice of medicine and this is unfair. Relief is highly desirable and it is thought that it is now timely to revise the original federal act so as to take out the burdensome restrictions which have been found to be not only unnecessary in practice but it is high time to make suitable additions to meet the issue in its real and proper place.

What has the study of this problem revealed? It has shown clearly that drug addiction is inexcusable in a nonmedical case. It has shown that addiction spreads through evil association. It has shown that many criminals are drug addicts. It has shown that these drugs constitute the armamentarium of the modern bandit in many instances. Police statutes therefore are needed, not only in National consideration but in State control and if we are to progress these statutes must be along similar lines and cooperative. A model act is now in process of preparation and it is hoped that this act will go a long way in aiding this problem.

If the United States will now lead in this problem it will have done much to show how to save the world from this devastating and burdensome scourge, of which there is none more menacing to health or society.

PLASTIC SURGERY IN FRANCE

Plastic surgery has been making headway in civilized countries. The war naturally gave it a great impetus. In France during the war, it may be said that Dr. Blake of New York had much to do with the advance of this branch of surgery. In New York Dr. J. Eastman Sheehan has been active in developing this art, as it may perhaps be fittingly termed with regard to his particular sphere of operation, the plastic surgery of the face, to which of course chief attention is paid by all plastic operators. To Dr. Sheehan's work in this direction reference has been made frequently in this journal. In Great Britain Mr. Gillies is the leading exponent of this method of making good, as far as possible, lesions or defects of the body due to disease, abnormal development, retarded development, or to injury.

An interesting paper on the subject was presented before the Section of Laryngology and Rhinology of the New York Academy of Medicine at a meeting on March 24, 1926, by Dr. Leon Dufourmental, laryngologist to the Pereire Hospital, Paris, and professor of facial surgery in the Dental School of France. An abstract of this paper was published in the *Bulletin* of the New York Academy of Medicine, May, last.

He pointed out that only a few surgeons practised this form of surgery in France. After Nelaton and Ombredanne, who made it a part of their work, the first to master it in France were Morestin and Sebileau. These conducted in Paris during the war the most important services involving the application of plastic surgery to war wounds. Outside of Paris, the heads of the hospitals devoted to this work were pupils of Sebileau, among them Lemaitre at Vichy and Dufourmental himself at Châlons-sur-Marne. At present there are two courses in which this specialty is taught: one at the Clinic of the Faculté de Medecin, in French, given by Professor Sebileau, and the speaker; the other in English at the International Clinic directed by Dr. Lemaitre, Mr. Gillies, Dr. J. Eastman Sheehan and Mr. Ferris Smith.

Dr. Dufourmental described the various methods employed in plastic surgery and pointed out that the

leading principle of reconstructive surgery is to respect the natural processes of healing. Many large mutilations have been repaired by guiding natural healing. When the result is inadequate it can be supplemented by surgical intervention.

As said before, the war advanced reconstructive surgery immensely and of course enlarged knowledge concerning it and increased the skill and ingenuity of operators. It has become an established branch of surgery, the scope of which will be widened as time passes on. Reconstructive surgery, now confined largely to the face for esthetic reasons, is being employed to correct lesions, blemishes and so on, in other parts of the body. It must be borne in mind that it is applicable to civil life. In these days, when machinery rules everywhere. when automobile accidents are frequent, and particularly in industry in which those suffering from injuries are numbered by the thousands, yearly, reconstructive surgery has a definite place.

WORK OF THE HEBREW SHELTERING GUARDIAN SOCIETY

The recently issued Biennial Report of Hebrew Sheltering Guardian Society of New York outlines the work of that organization and shows the progress made in methods, practical care and ideals during the past few years. The home, which is a modern cottage plan institution for the care of dependent Jewish children, is located at Pleasantville, Westchester County, New York. The officers of the society are Adolph Lewisohn, president; Herman W. Block, chairman of the administration committee; and Samuel D. Levy and Louis Seligsberg, vice presidents.

Only a few years ago the Hebrew Sheltering Guardian Society was a congregate institution in New York city, housing between six and seven hundred children under one roof, and boarding out approximately two hundred additional children who were regarded as undesirable for institutional care, or as still too young to be transferred to the institution. In 1912 the society gave up its congregate housing plan and moved to Pleasantville, but retained approximately the proportion of children housed to those boarded out. Today, however, these relative positions have been reversed. The cottages at present house three hundred and the foster homes under the supervision of the Home Bureau five hundred and fifty. This change is the result of a definite progressive social policy that children who cannot be kept in their own homes are preferably placed in good foster homes, adequately supervised by trained social workers, rather than in even the best type of institution.

Another change has been in operation since the Jewish Children's Clearing Bureau was opened in New York four years ago to investigate applications for placement. Ever since that time, great care has been taken to prevent the removal of children from their homes merely because of poverty. This means that the children now received for care may be roughly classified as follows: a few full orphans; a large number of children whose parents are temporarily mentally or physically disabled; children whose parents are improper guardians from the standpoint of morals; and an increasingly large number of children who present various types of behavior problems that cannot be solved in their homes or present environment. It has been found that both in the institution at Pleasantville and in the Home Bureau the task of adjusting the child of bad heredity or poor social background and the children who are in themselves problems, is becoming increasingly great and difficult. To meet this situation, a mental hygiene department has been established at Pleasantville under the direction of Dr. Clarence P. Oberndorf, chief psychiatrist at Mt. Sinai Hospital. Assisting Dr. Oberndorf are two visiting psychiatrists and three psychiatric social workers. The function of this department is three fold: first and foremost, by early detection of slight deviations from normal behavior, to adjust the situations that give rise to these, whether caused by environment or by conflict in the child's mind, thus forestalling and preventing if possible more serious maladjustments in the future; second, when such maladjustments have gone beyond the early preventive stage, to give the best possible psychiatric therapy for such conditions; third, to decide whether any given maladjusted child is such that it cannot be retained at the institution without real detriment to the other children.

Accurate and detailed clinical records as a means of evaluating progress are being kept, and a system of recording and filing of data is being devised with the object of making these records as nearly uniform as possible. "In summing up what the department has accomplished," says the report, "it can be said that excellent contacts have been made with those whom we have met so far, and that we have made a promising beginning in the work. No immediate and sudden changes are to be expected, nor are they desirable in the institution as a whole or in the individuals treated. What changes we hope to accomplish will come gradually, and our aim is to build a firm and secure foundation, of which we are now laying only the first stones."

During the past two years the Hebrew Sheltering Guardian Society has adopted the policy of accepting children whose guardians can pay in part for their maintenance and care. These are children who for various reasons must be removed from their homes, yet on account of their families' incomes are not jus-

tified in claiming public support. A large number of free cases are also admitted as a matter of course. These are to some extent children, who, were it not for their free admission, might be brought to the attention of the public authorities as dependent aliens, likely to become public charges and therefore liable to deportation. Included among the free cases are of course children as to whom there is no question of deportation, but who, if placed at all, must be placed on the free list because they do not fit into the categories of children eligible for commitment by the Department of Public Welfare or the Children's Courts, and have no relative able to pay for their care.

Much is made of recreation and outdoor sports and occupations. Some of these are gardening, bus rides, hikes, tennis, community singing and dancing, festivals and carnivals, football, hockey, basketball, skiing, skating, baseball, cycling, boxing, and other sports and games. Camp Sunny Corners, a few miles from Peekskill, provides the children with summer outings. A recent commission appointed by the National Educational Association formulated a set of cardinal principles of education which have been adopted by the association as the main objectives of the modern education of the child in the United States. These are: 1, health, physical and mental; 2, command of fundamental processes; 3, worthy home membership; 4, vocation; 5, citizenship; 6, worthy use of leisure; 7, ethical character. The Hebrew Sheltering Guardian Society has taken these seven principles as the basis of its educational plan, and is applying them with marked success.

THE FIRST PRESIDENT OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA

Dr. John Redman, the first president of the College of Physicians of Philadelphia, is the topic of an interesting and sympathetic sketch by Dr. William S. Middleton in the fall number of the *Annals of Medical History*. After an apprenticeship under Dr. John Kearsley, Sr., of Philadelphia, an apprenticeship which included among its functions those of servant, messenger boy, prescription clerk, nurse and assistant surgeon, Redman practised medicine for several years in Bermuda, and then spent a year of study in Edinburgh. He took his degree in medicine at the University of Leyden and studied in Paris and London before returning to Philadelphia, about 1750. He at once took a prominent place in practice there and rose to leadership. He was the first president of the College of Physicians, a trustee of the College of Philadelphia until it was merged in the University of Pennsylvania. For twenty-nine years he was on the staff of the Pennsylvania Hospital.

Notwithstanding his delicate health, he lived to be eighty-six years old. He was an active participant in all medical affairs of the time and his report on the yellow fever epidemic of 1762 is the most complete and informing papers extant on that subject. He acted as preceptor to many physicians who later won distinction. Doctor Middleton gives an interesting survey of medical affairs in Philadelphia during Redman's life, in all of which he took an active part.

THE ROSS INSTITUTE AND HOSPITAL FOR TROPICAL DISEASES

On July 15, 1926, the Prince of Wales opened the Ross Institute and Hospital for Tropical Diseases situated on Putney Heath, a London suburban district a few miles from London. The institute has been founded to commemorate the twenty-fifth anniversary of the discovery by Sir Ronald Ross of the method of transmission of malaria to human beings. Its objects are to carry on research work in the prevention and treatment of tropical diseases and to assist medical men to carry out research work.

The building, formerly known as Bath House, provides three laboratories, two wards for patients suffering from tropical diseases, accommodation for nurses and a library. Investigations of diseases of tropical interest have already begun, and it is proposed to carry out researches on cancer and smallpox.

In the course of his opening speech the Prince of Wales quoted the saying of a well known writer to the effect that it was not too much to say that Ronald Ross had made one third of the world habitable.

MOSQUITOES PREFER BLONDES

Like the men depicted in a recent popular novel, it seems that mosquitoes too prefer blondes. While evidence goes to show that mosquitoes are more apt to pay their unwelcome attentions to fair rather than dark people, it appears to have been proved conclusively that there are three classes of persons as far as mosquitoes are concerned: 1, Those extremely sensitive to infection by mosquito bite; 2, those who might be called normal, and 3, those who might be called resistant. No reasonable explanation is forthcoming as to why this is so. One suggestion is that glucose in the blood may enter into the question. The subject is interesting and of some importance, and any data on the point which might be contributed by those who are concerned with the point and who have opportunities for testing the susceptibility of certain individuals, would be rendering a service of pathological value.

Obituary.

JOHN GEORGE ADAMI, C.B.E., M.D., F.R.C.P.

Liverpool, England

John George Adami, a pathologist of international fame, as well known in this country as in England and perhaps better known in Canada than in his native land, passed away on September 29th last in a nursing home in Liverpool. He was born in Manchester on January 12, 1862. His father was a Manchester man and his mother was the sister of Professor D. J. Leech, a well known Manchester pharmacologist. He was educated at the grammar school and Owen's

College, Manchester, and at Christ's College, Cambridge, where he took a first class in the Natural Science Tripos and was Darwin prizeman. He studied also in Paris and Breslau, and having taken his degree in medicine at Cambridge became house physician to the Manchester Infirmary. He then went back to Cambridge as demonstrator of pathology, was awarded the John Lucas Walker studentship, and was made a Fellow of Jesus College. At Cambridge Adami entered with enthusiasm into research work in collaboration with Smart Roy, who had been trained by Cohnheim. Their observations in comparative pathology were of considerable value and Adami was recognized as a coming man. Roy and Adami published the *Physiology and Pathology of the Mammalian Heart.*

When only thirty years old he was given the post of Strathcona Professor of Pathology and Bacteriology at McGill University, Montreal. He was an excellent teacher, both in the classroom and the laboratory, his scientific gifts being combined with an extraordinary aptitude for business and an unlimited appetite for work. In Montreal he associated himself actively with most of the movements for the improvement of health and on the outbreak of the war had attained a position of eminence in Canadian medical life.

At Montreal Adami was the first professor of pathology at McGill and developed the department. He did not do much laboratory work himself but was greatly interested in the possible relation of intestinal bacteria to cirrhosis of the liver.

Perhaps, however, it was as a writer that Adami's name will live. He was one of the original contributors to Allbutt and Rolleston's *System of Medicine.* His article on inflammation therein was on the whole the best contribution. It is a classic which should be read by all students anxious to know about pathology. Next his great *Textbook of Pathology* appeared. The *Principles of Pathology* came out in 1909 in two volumes. It was hailed as the best presentation of general pathology in the English language. Its author was well equipped for the task, he had worked with Roux in Paris, with Heidenhain in Breslau, and with Michael Foster and Roy in Cambridge. Moreover, he wielded a forceful pen, and was a master of clear and expressive English. No second edition was published as this would have entailed work too great for any one man. Four years after Adami and John McCrea, his colleague at Montreal, brought out a *Textbook of Pathology* in one volume which has had a great vogue and has been republished in revised form.

In 1917 he delivered the Croonian Lectures before the College of Physicians of London. These dealt with evolution and with additions were published in book form. They considered biology chiefly and criticized severely the unsatisfactory state of opinion on the questions of variation and adaptation. He also sent out from his Montreal laboratory contributions to the pathology of the heart and bloodvessels and a classification of tumors which appeared in the *Journal of Pathology,* 1903, Vol. 8, p. 243. His *Principles of Pathology* was his greatest work and its only fault was that it was in advance of the times. But Adami's views were based on a sure foundation and in the main they will be accepted as such.

On the outbreak of war he placed his services at the disposal of his country serving in the Canadian Army Medical Corps with the rank of colonel and became Assistant Director of Medical Services. He was also historical recorder of the Canadian Expeditionary Force. In this capacity he showed himself an unsparing critic when he thought that criticism was called for. After the war had ended he accepted the post of Vice-Chancellor of the University of Liverpool and interested himself in the affairs of the university and the city with as great energy and zest as he had displayed in the same direction in Montreal. During the seven years he was at Liverpool it is acknowledged on all sides that he did magnificent work for Liverpool University. With the students he was very popular. In this country Dr. Adami was known in medical circles everywhere and he had several offers of posts in universities in various states. He possessed not only the highest scientific acquirements and gifts but possessed in addition that boundless energy and that business acumen which commend themselves to Americans. In our issue for August 15, 1926, is published the last address that Dr. Adami gave, dealing with the nature of malignancy. It may be said that it is a brilliant presentation of the subject.

Naturally Adami received many academic honors. He was an honorary F.R.C.S. of England, of Scotland, and of Canada, an honorary M.D. of American universities, and an honorary LL.D. of other American universities. Besides being a Fellow of Jesus College, Cambridge, he was a Fellow of Christ's, his own college. He had been president of the Canadian Association for the Prevention of Tuberculosis, president of the Association of American Physicians and Fothergillian Medallist of the Medical Society of London.

CHARLES EDWARD NAMMACK, M.D.

New York

Dr. Charles E. Nammack, who died at his home in East Fifty-ninth street on October 4th, was for many years one of the leading physicians of this city. He was born in New York seventy years ago, and was graduated from University and Bellevue Hospital Medical College in 1881. He was made a Bachelor of philosophy by St. Francis Xavier College, and a doctor of philosophy by Fordham University, and a doctor of laws by Fordham University. He had been clinical professor of medicine at Cornell Medical School since 1898, was for twenty-three years attending physician to the out-patient department of the New York Hospital, surgeon to the New York Police Department for thirty-three years, and visiting physician to Bellevue Hospital since 1896. He had also served on the staff of St. Vincent and St. Lawrence Hospitals in New York, and St. Joseph's Hospital, Yonkers.

Dr. Nammack contributed many valuable articles to the New York Medical Journal, the *Catholic Encyclopedia, The Messenger,* and the *St. Vincent de Paul Quarterly.* He was a member of the leading medical organizations, both local and national, and of many societies. He is survived by his son, Dr. Edward H. Nammack.

Das Kurhaus, Wiesbaden

A Study Tour of Europe in 1926

RICHARD KOVACS, M.D.
New York

(*Concluded from page* 439)

ROLLIER'S CLINIC

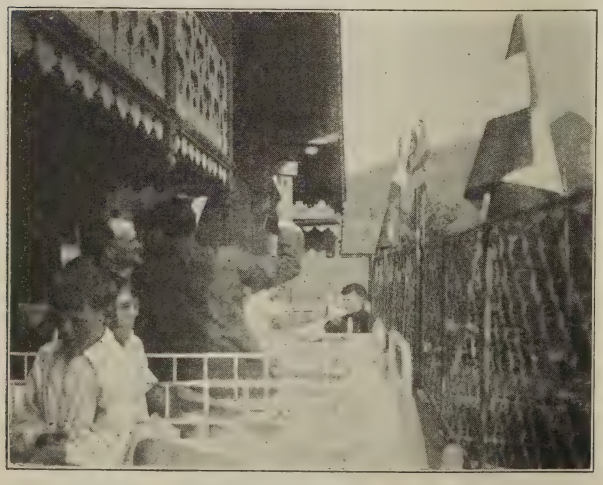
The visit to Rollier's Clinic in Leysin was one of the most impressive of our trip. We motored up from Lausanne, along the shores of beautiful Lac Leman, passing Vevey, Montreux, and the famous Chillon castle. The road then winds up along a wonderful gorge, to a plateau at an altitude of almost 4,500 feet, surrounded by still higher towering mountains, snow covered even in summer, and here lies the village of Leysin. Rollier started his first clinic for the treatment of all types of surgical tuberculosis by heliotherapy in 1903 here, and by his untiring enthusiasm built up a wonderful organization and won the confidence of the medical world which now recognizes his methods as standards. The main explanation of Rollier's results is that instead of considering surgical tuberculosis merely as a local ailment, he directed treatment towards the complete reconstruction of the whole organism, and has found systematic general insolation in the pure and bracing mountain air most efficient for both general and local treatment. Besides there is a painstaking attention to general régime, a mainly lactovegetarian and fruitarian diet, with meat only once a day and alcoholic drinks and smoking forbidden. Plaster casts are done away with, instead there is immobilization in bed; under insolation the atrophied or swollen limbs show wonderful development. Cold abscesses often absorb spontaneously—if not, are evacuated by punctures, never by incision. Several cases of cold abscesses operated on the outside for appendicitis were seen. All cases are controlled by x rays and exact laboratory procedures. The work cure (occupational therapy) forms a most important part of therapy. The main clinic is *Les Frénes* which, like the others, has open balconies where the patients are directly moved out from their rooms. This clinic and the original clinic *Le Chalet* are owned by Dr. Rollier; other clinics are owned by various authorities, and by individuals, being adapted or built especially for the purposes of heliotherapy, and spread out picturesquely around the village and its meadows. The clinics, singly or in groups, are manned by Dr. Rollier's assistants, but each and every individual case is invariably attended by Dr. Rollier himself. There are suitable accommodations for the well to do and the poor, and Dr. Rollier states that better and quicker results are obtained with the latter class, as it obeys dietetic regulations more faithfully. The children's clinics are particularly impressive, on account of their manysided activities and their fine spirit. At the exquisite luncheon tendered to our party, groups of children appeared at intervals rendering clever sketches and songs. There were quite

Leysin village. The building in the centre at the top is Les Frênes, the main clinic of Rollier

a number of American patients among the adults as well as among the children.

PARIS

A week was spent in Paris where the Association for the Development of Medical Relations and the Faculty of Medicine, under the leadership of Professor Hartmann, arranged for clinical visits. The history of the medical institutions is invariably interwoven with the history of France. The Hôtel Dieu is the oldest hospital of Paris, and possibly of Europe, situated on the Island of the Cite. It began in the seventh century as a refuge for the aged, incapable and sick. Four to six persons occupied beds of straw upon the floors in thickly crowded and unheated halls. Among the eminent men of medicine and surgery who have practiced and taught at the Hôtel Dieu are Dupuytren, See Dieulafoy, Chomel, and Trousseau. The name of Grisolle is especially significant, because of the fact that he provided a bed for each patient, heating for the wards, and operating rooms separated from open wards occupied by the patients. Professor Hartmann demonstrated the surgical service and the radium x ray, mechanotherapeutic and electrical departments. Professor Gilbert, chief of the medical service, showed a three way evacuation apparatus,



Rolier showing x ray films to Dr. Fred H. Albee, in Boy Scouts pavilion.

practically applied in a case of pleuritis. This instrument provides for withdrawal of liquid, injections, and manometer attachment, and is applicable for transfusions, evacuations, and all sorts of such procedures. The manometer is considered of great importance, as are also the graphic curves which record changes in pressure.

The Hôpital Cochin is quite modern and we saw the surgical clinic of Delbet and the medical of Widal. The Pauchet clinic is especially designed for instruction. Pauchet has particularly developed regional (paravertebral) anesthesia, using novocain.

The world famous radium work of Mme. Curie is now housed in the new Institut Curie, which was demonstrated by Professor Regaud.

We next visited the Hospital of the Val de Grace which is especially devoted to the military and naval sanitation. Records are still being received referring to the recent war. The initial part of the French historical reports on the war are just being presented. The museum contains numerous specimens obtained from the war cases. Wax models show a variety of vicious postures produced by projectile injuries of muscles and nerves. Part of the hospital occupies

One balcony of Les Frénes, main clinic of Rollier

the site of an ancient convent, and the cloisters, still existing, were shown by Professor Dopter, Curator.

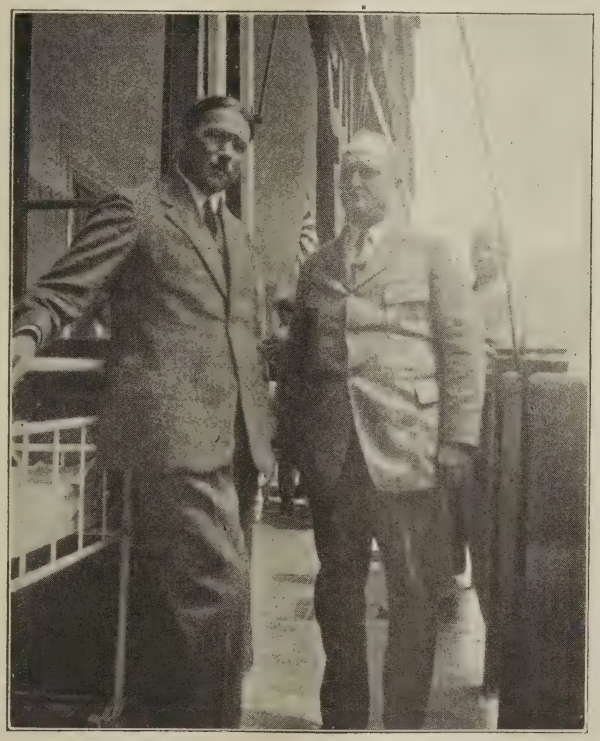
The Faculty of Medicine, with its wonderful museum and library, is of great professional interest, and we also visited the adjoining laboratory of pathological anatomy and its famous dissecting rooms. Anatomy is the most exacting branch of the French medical curriculum, and its lecture rooms are particularly well equipped for teaching. A glass of champagne was served by the Bienvenue Francaise in the Council Room of the Faculty, hung with beautiful and rare Gobelin tapestries.

The Salpetrière was converted by Louis XIV and Mazarin in 1660 from a saltpeter factory into a refuge of the lawless simulators and criminals, as described in the classics of Victor Hugo and Dumas. Now it is a great hospital for neurology (Guillain), neuropsychiatry (Crouzon), and surgery (Gosset). Bourguignon's laboratory for exact methods of electrical testing (chronaxie) is attached, also the fine radiological service of Ledoux Lebas. We stood in reverence in Charcot's library and lecture

room, the latter containing the famous painting showing Pinel striking fetters off the helpless insane. Opposite these ancient buildings is the modern Hôpital de la Pitie, where the medical clinic of Vaquez was visited; special postgraduate courses of electrocardiography and radiology of the heart are given here by Dr. Geraudel and Dr. Bordet. In the surgical clinic Dr. Lenormant showed cases of Pott's disease, treated by the Albee operation. The unexpected presence of its originator, our president, created a small stir.

The Hôpital St. Louis is a great dermatological hospital, world famous on account of its museum, a very large collection of excellent resin models. The director, Professor Jeanselme, also demonstrated the fine laboratory and therapeutic equipment, which include actinic rays, high frequency, etc.

In the Pasteur Institute and Hospital Professor Calmette received us, assisted by Dr. Harry Plotz of New York, a regular member of the staff. We stood in reverence before Pasteur's tomb and saw his original culture media, which remained sterile for more than fifty years, thus still disproving spontaneous generation of bacteria. In the library we saw the urn containing Metchnikoff's ashes, which, according to his will, is placed on top of one of the bookcases. In the laboratories extensive cancer research work on different types of monkeys is going on. Our last visit was to the splendid new building of the American Hospital at Neuilly, just outside the city gates. Dr. Gros, the physician in chief, as well as the entire staff, were our hosts at tea. Dr. Albee donated his newly designed operating table to the hospital. A model physical therapeutic department forms part of the excellent equipment.



DR. ROLLIER and DR. FRED H. ALBEE

* * *

Our official program ended in Paris, as about half of the party thence sailed for the home shores. The remainder spent a week in London, with some individual visits to medical institutes. The Fellowship of Medicine and Postgraduate Medical Association provides a complete weekly list of postgraduate medical opportunities.

We arrived back in New York on August 8th, having traveled two months. A volume containing a detailed account of our Study Tour, including full medical data, is being prepared by the Committee on Publication, and special articles on the surgical and physical therapeutic clinics are also under work.

SUMMARY

A medical study trip as described, with a few days' stay at the various centres, will give its participants a fairly good survey of the medical work in general, and also allows attention to special problems to the exclusion of others. Very instructive immediate comparisons can be made between the various localities. As medical men are at once on common ground everywhere, the personal contacts established usually well outlast the trip. Due to the interest in group visits, international goodwill is, as a rule, markedly promoted both within the profession and in the lay press.

We find that on the continent medical education and institutional work is, on the whole, under state or municipal control, reasonably free from politics and contiguous. A fairly good salary and the respected social position encourages men to devote themselves more or less exclusively to teaching. War conditions have undoubtedly handicapped some centres, but on the whole the excellent clinical teaching and laboratory work goes on as usual. The fact that postmortem examinations abroad are the rule and not the exception as with us, is a great help towards exact clinical diagnoses. Since the war a marked improvement in the training and service of nurses was noticed. Comparing conditions, however, we can be justly proud of the present American status in hospital construction, medical education, including postgraduate facilities and laboratory research. There is no end of interest displayed abroad towards our medical institutions, and it is to be hoped that a stabilized world exchange will soon permit European medical men to visit America more frequently.

Aside from the great general cultural interest of a European trip and of its broadening effect along medical lines, there is a great deal in some of the clinics abroad that is unique and cannot be appreciated until seen on its own ground. Americans are assured of a cordial welcome everywhere.

223 East Sixty-eighth Street.

Italian Congress on Radiology.—The seventh Italian Congress of Medical Radiology was held in Naples, on October 14, 15, and 16. Among those who presented papers were Professor Adinolfi, of the University of Naples; Professor Rossi, of Parma; Professor Epifanio, of Palermo, and Professor Lupo, of Turin. An interesting scientific exhibit was held.

News Items.

New Building for Wyckhoff Heights Hospital.—Excavation is under way for a combined two story pathological laboratory and nurses' dining room on the Stockholm Street side of Wyckoff Heights Hospital.

Dr. Baker at Sing Sing.—The newly reorganized psychiatric department at Sing Sing Prison is in charge of Dr. Amos T. Baker, formerly superintendent of the New York State Reformatory for Women at Bedford Hills.

New Hospital Building.—The corner stone of St. John's Hospital on Herkimer Street, Brooklyn, was laid by Bishop Stires on October 11. The building is to cost more than $1,000,000.

Madrid to Have Psychopathic Institute.—Recent announcements in the Spanish press have stated that the new budget for hygiene in Spain has provided 2,000,000 pesetas for the construction of a psychopathic institute in Madrid.

Syracuse Has Whooping Cough Clinic.—The *Weekly Bulletin* of the Syracuse Health Department reports a gratifying response to the opening of its whooping cough clinic. Cases are classified, studied and treated according to the symptomatology and progress of the disease.

The New Medical Centre.—Dr. Claude Regaud, a director of Mme. Curie's radium institute in Paris, after a recent visit to the New York Medical Centre now under construction, said that it was the most astonishing thing he had seen in all his career and asked for a complete set of plans to take back with him to France. He thought that there were great possibilities to be accomplished by following the New York plan of bringing the hospitals together and coordinating their work.

Dinner for Dr. Downing.—A testimonial dinner to Hon. Augustus S. Downing, assistant commissioner and director of professional education of the New York State Department of Education, will be tendered at the Hotel Commodore, on the evening of October 27th. This will be in celebration of the many years of successful efforts by him to raise medical and other professional standards. Dr. Orrin S. Wightman is chairman of the committee on arrangements, and applications for seats should be made at once to him.

American Society for the Control of Cancer.—The campaign of this society for raising an endowment of $1,000,000 for educational purposes has resulted in a fund of about $443,000 up to the present time. This fact was announced at a luncheon held on October 13th at the Hotel Plaza. Dr. Howard Canning Taylor, president of the society, being the guest of honor. The principal speaker was Dr. George E. Brewer, who praised the work of the society in educating the public as to preventive measures. Dr. Taylor said that there were fully 150,000 deaths from cancer in the United States annually.

New Site for Lutheran Hospital.—The Lutheran Hospital of Manhattan has announced the purchase of an entire city block of land on Washington Heights at 187th Street and Bennett Avenue, where a new hospital building will be erected. The first unit, accommodating two hundred beds, will cost $1,000.000. A campaign will soon be started for the raising of $750,000 which, it is hoped, will be donated by December, so that the construction of the new unit may be commenced in the new year. Provision for persons of moderate means is the special aim of the Lutheran Hospital.

New York Plans School Medical Bureau.—The Department of Education of the City of New York is planning the organization of a medical bureau, one function of which will be to centralize in one group the various medical examiners, now assigned to special tasks, under the supervision of the chief of the Medical Examining Board, Dr. Emil Altman, and so would be subject to assignment by him upon call. Under the proposed plan, Dr. Altman would assign medical examiners to examine applicants for license to teach, and, in cooperation with the associate superintendent, would assign examiners to examine members of the teaching and supervising staff, the administrative staff, and the staff of attendance officers in the discretion of the Superintendent of Schools, make report and recommendation thereon, and suggest methods of improving the physical condition of the members of such staffs.

Death of Westchester County's Oldest Physician.—Dr. H. E. Schmidt, the oldest physician in Westchester county, died at his home in White Plains on October 11, at the age of 92. He was born in Germany, organized the first hospital in Japan and began the practice of medicine in White Plains in 1863.

Opening of New Building.—The formal opening of the new building of the New York Academy of Medicine will be celebrated by an elaborate three day programme commencing on November 18th. The new building at Fifth avenue and One Hundred and Third street consists of a main building approximately 100 feet square and six stories high; an extension sixty by seventy-six feet, which is three stories high and a stack fifty-eight by forty feet. The removal of the books to the new library which began in July is nearly completed and the new library will be open by November 1st.

Clinical Catalogue.—A comprehensive catalogue of "Opportunities for Clinical Study in Hospitals of New York City" has just been issued by the New York Academy of Medicine which will furnish copies without charge to physicians who are interested. The Committee on Medical Education maintains at the Academy a Bureau of Clinical Information where detailed information is available regarding opportunities for graduate medical study in Greater New York, and also in other cities of the United States, Canada and Europe. The committee publishes a daily bulletin giving the operations to be performed in seventy-five hospitals and the medical clinics to be held in twenty-five hospitals. This bulletin will also be mailed free to physicians interested.

Montpellier's Journées Médicales.—The city of Montpellier, France, celebrates this year the centenary of the establishment, in the old *Universite de Medecine,* of its *chefs de clinique.* The day chosen for the celebration is November 3d. This event will precede the three *journées médicales* which have been arranged by Dr. Desfour, for November 4th-6th. The fourth will be devoted, according to the announcement, to contemporary science as a whole, and specifically to the commemoration of the centenary of the discovery of brome; the fifth will be devoted to military hygiene and sanitation; and the sixth to legal medicine and its various phases and problems. The *journées* will be succeeded by a day, Sunday, November 7th, of excursions to various points of interest.

Mental Hygiene in Italy.—The *Lega Italiana per la Prevenzione delle Malattie Nervose e Mentali* has been founded in Rome. Its purpose is analogous to that of similar leagues already established in the larger countries of Europe and America. Honorary chairmen are: Prof. Leonardo Bianchi, senator, and Professors Morselli and Tanzi; active chairmen are: Professors Ettore Levi, Ferrari, and Medea. The following chapters have already been organized and have begun work: Lombardy (Prof. Medea), Piedmont (Prof. Lugaro), Ligura (Prof. Vidoni), Emilia (Prof. Ferrari), Marche (Prof. Modena), and Abruzzi (Prof. Del Greco). At Rome a Latium chapter has been established, which is housed in the *Instituto Italiano d'Igiene Previdenza ed Assistenza Sociale,* under the chairmanship of Professor De Sanctis of the University of Rome.—*Mental Hygiene Bulletin.*

Gifts and Bequests.—Through the will of the late Kate S. Richardson, widow of Edward W. Richardson, a million and a half dollars were left to welfare institutions and organizations. The Society of the New York Hospital received $587,978; the Henry Street Settlement, $200,000; the United Hospital Fund of New York, $293,988; the New York Society for the Prevention of Cruelty to Children, $50,000; the Association for the Aid of Crippled Children, $60,000; the National Child Welfare Association, $30,000.

The will of the late Alfonso de Navarro provided that seventeen welfare institutions receive bequests. Among these were the New York Hospital, St. Elizabeth's Hospital, and St. Vincent's Hospital, each of which received the sum of $5,000.

The University of Chicago has received a bequest of $600.000 from the estate of Miss Helen Culver, for the further development of biological science.

By the will of John McCaffery the Hospital of St. Elizabeth of Hungary, New York, received six thousand dollars; the New York Society for the Relief of the Ruptured and Crippled, the Servants for the Relief of Incurable Cancer, St. Vincent's Hospital, New York Ophthalmic Hospital, for the purchase of appliances and instruments for the care or comfort of deformed or crippled children.

Personal.—Surgeon J. W. Schereschewsky of the U. S. Public Health Service attended the recent Symposium on Cancer held at Lake Mohonk.

Dr. Hyman D. Silver, who has been spending the summer in Europe, has returned to New York and is located at 1384 Grand Concourse.

Dr. Joseph Rivière of Paris and Dr. Franz Nagelschmidt of Berlin have recently been visiting in New York, whence they went to Chicago and Detroit to study the progress of physiotherapy.

Dr. Stephen J. Spitzer has been appointed adjunct attending surgeon to Sydenham Hospital.

Prince Asani of Bangok, grandson of a former King of Siam, has enrolled as a freshman at Harvard, where he will study medicine. He is nineteen years of age. The Prince was accompanied to Cambridge by Dr. Francis B. Sayre, formerly legal adviser of King Rama VI of Siam. Dr. Sayre is now professor of law at Harvard.

Dr. E. Garnsey Brownell sailed for Europe on September 25th. His first stay will be in France.

Dr. Alexander W. Mackensie, senior surgeon of the Cunard fleet, who has been attached to the *Mauretania* since the World War, has retired from active service. Dr. Mackensie had served twenty-five years on the Cunard Line, and before that was surgeon of the White Star fleet. He was on the Franconia when, during the war, she was torpedoed in the Mediterranean, and he received an injury to his right hand from a piece of German shell. He was born in Edinburgh and graduated from the university of that city. He was a warm friend of many of the members of medical profession and others who have found him a most congenial companion in crossing the Atlantic for more than forty years.

Dr. Ferenczi, of Budapest, has arrived in New York, where he will give a course of lectures at the New School for Social Research. He has not been in this country since seventeen years ago, when he accompanied Freud and lectured at Clark University.

Society News and Notes.

Professor F. Neufeld, Director of the Robert Koch Institute for Infectious Diseases, Berlin, will deliver the first Harvey Society Lecture at the New York Academy of Medicine, on Saturday evening, October 30, 1926. His subject will be Recent Investigations in Tuberculosis.

* * *

At the annual meeting of the National Association of Police and Fire Surgeons, and Medical Directors of Civil Service Commissions of the United States, held in Philadelphia on September twenty-second, Dr. Daniel J. Donovan, of New York, was elected president. The next annual meeting will be in Los Angeles, California.

* * *

The Woman's Medical Association of New York announces that the night of the meeting has been changed from the third to the second Wednesday night of the month so as not to conflict with the meetings of the New York Academy of Medicine.

* * *

Among delegates to the recent conference in Washington of the International Union of Pure and Applied Chemistry who visited New York City were Dr. Paul Lapie, rector of the University of Paris; Prof. Paul Sabatier, of the Institute; Prof. Gabriel Bertrand of the Sorbonne; and M. Marc Bridel of the Museum. A reception and dinner to the delegates was given by the *Alliance Francaise de New York* at the Hotel Brevoort.

* * *

The New York Cancer Association had the privilege of showing to the foreign delegates to the Mohonk Cancer Symposium their recently organized research laboratories in the course of construction at 250 West Forty-ninth Street. The visit and accompanying tour were under the direction of Dr. Walter H. Conley, medical superintendent of the Department of Public Welfare. The party also visited the Cancer Clinic at 124 East Fifty-ninth Street and the Cancer Hospital on Welfare Island, both of which are maintained and conducted by the Department of Public Welfare.

* * *

During the recent session of the American Electrotherapeutic Association at Atlantic City, Dr. William B. Snow of New York City was given a testimonial dinner at the Hotel Ambassador in celebration of the twenty-fifth anniversary of his editorship of Physical Therapeutics. He was presented with a bronze desk lamp by his friends in the association.

* * *

Colonel S. Lyle Cummins, C.B., C.M.G., M.D., LL.D., A.M.S.(Ret.), the David Davies professor of tuberculosis at the Welsh National School of Medicine, and principal medical officer of the Welsh National Memorial Association, will deliver on Friday evening, October 22, at the New York Academy of Medicine the 1926 Hermann M. Biggs Memorial Tuberculosis Lecture. His subject will be Clinical Differences in the Course of Tuberculosis Seen in Various Age Groups and Races. The address is to be given under the joint auspices of the Medical Society of the County of New York and the New York Tuberculosis and Health Association. The lecture is given annually under the terms of an endowment created by Mrs. Frances R. Biggs in memory of her husband, the late Health Commissioner of the State of New York.

* * *

The Medical Society of the County of Erie and the Buffalo Academy of Medicine joined in a memorial meeting in honor of the late James A. Gardiner on October 6th. The meeting was held immediately following the stated meeting of the Buffalo Academy, at which Dr. Francis I. Carr. F.A.C.S., spoke on Fractures in General.

* * *

The National Association for Music in Hospitals announces that it has received sufficient donations from public spirited women in New York City to enable them to train and send musicians to institutions requiring this service. Free scholarships are offered. Information may be obtained at the association's headquarters at the Steinway Building, West Fifty-seventh Street.

* * *

The New York and New England Association of Railway Surgeons will hold its thirty-sixth annual meeting at the Hotel Commordore, October 22d-23d.

* * *

The beautiful new building of the New York Academy of Medicine, located on the south east corner of Fifth Avenue and 103d Street, is nearing completion.

* * *

The Pennsylvania Tuberculosis Society has appointed Dr. William P. Brown medical secretary. Dr. Brown has been occupying the position of medical director of the county sanatorium and assistant director of the bureau of tuberculosis in Cattaraugus County, N. Y. where he has been helping to conduct the five year demonstration of the Milbank Memorial Fund and the New York State Tuberculosis and Health Committee.

* * *

The Adirondack Fund for the Tuberculous has recently broken ground for the new sanitarium to be known as the Northwoods Home of the Fund. Colonel Walter Scott of New York was master of ceremonies. Special cars from New York brought a theatrical group among whom were the vaudeville artists who appeared later in a big benefit performance staged at the new Palace Theatre at Lake Placid for the benefit of the sanitarium fund.

* * *

The Commonwealth Fund, established by Mrs. Stephen V. Harkness, is making studies in eleven northern and midwestern states to determine the proper location of the third rural hospital to be constructed under the cooperative program instituted by the Fund last winter. The first of the hospitals is to be at Farmville, Va., and the second will also be in the South, although the exact location has not yet been chosen. In planning the third hospital, correspondence is being carried on with many cities and towns of the North and Northwest. When applications are approved, the Fund will donate two thirds of the cost of construction and equipment, and the chosen community will be responsible for one third and upkeep.

Book Reviews

PEDIATRICS

Diseases of Children. A Short Introduction to Their Study. By Hector Charles Cameron, M.A., M.D. (Cantab.), F.R.C.P. (Lond.). Oxford Medical Publications. London and New York: Humphrey Milford (Oxford University Press), 1926. Pp. ix-199.

The purpose of this little pocket edition of a book on children's diseases is admirably expressed by the common purpose of the books of the Oxford Medical Handbooks, namely, "to deal shortly with the fundamental principles which underlie their subjects, and to illustrate these by their applications in general practice. They are in no sense to be regarded as short textbooks, but as giving a general survey, on broad lines, . . . and of their relations with each other."

Instead of following the manner of the usual textbook in giving the etiology, pathology, diagnosis and treatment of disease, the author hits the high points of pediatrics and emphasizes those that require special study. The style is lucid and most engaging. This book may unhesitatingly be recommended to medical students as an introduction to pediatrics and also to advanced students as supplementary reading. Even the general practitioner will be well rewarded by reading it, as it contains much that cannot be found in the more pretentious books on the subject. It presents an approach to the subject different from that usually followed and gives a wide perspective of the fundamental principles of pediatrics.

MEDICAL EDUCATION

Methods and Problems of Medical Education: Series 2-4. Division of Medical Education of the Rockefeller Foundation. 3 Volumes. Illustrated. New York: 1924-1926.

In presenting the second, third and fourth volumes of its Medical Education Series, the Division of Medical Education of the Rockefeller Foundation has followed the same plan and idea as were incorporated in its first. This is stated as the collecting and publishing from time to time of brief descriptions of clinics, laboratories, and methods of teaching in different parts of the world in order that the information in convenient form may be brought to the attention of those most interested, and with the hope that the material may be of assistance to those planning improvements in buildings and methods.

Series II contains a section by Dr. Milton J. Rosenau entitled The Sanitary Survey as an Instrument of Instruction in Medical Schools, followed by a detailed sanitary survey of Rochester, New Hampshire, made in 1922 by Shields Warren. The Third Series contains illustrated descriptions of the Department of Physiology and of the Molteno Institute for Research in Parasitology of the University of Cambridge, England; the laboratories of physiology of the Harvard Medical School; the Physiological Institute of the University of Groningen; the Departments of Physiology and of Pharmacology, and the Laboratory of Anatomy of Western Reserve University; the Department of Anatomy of the University of Leiden; *die Dr. Senckenbergische Anatomie der Universität Frankfurt am Main; l'Institut d'Anatomie et l'Institut d'Histologie de l'Université de Strasbourg;* the Pathological Institute of McGill University; the Departments of Pharmacology, of Biochemistry and of Surgery of Peking Union Medical College; and the Department of Physiological Chemistry of the Yale University School of Medicine. Series Four consists of a detailed and fully illustrated description of the record room, unit history system, and follow up system of the Presbyterian Hospital of the City of New York. The preface states that Professor W. W. Palmer, physician in chief of the Presbyterian Hospital and professor of medicine in Columbia University, assisted in preparing this publication. The section on the unit history system is by Dr. H. Auchincloss, visiting surgeon to the hospital, and the section on the follow up system by Dr. James H. Corscaden, assistant consultant in gynecology. An appendix gives a reproduction in facsimile of one typical unit history.

SPINAL CORD TUMORS

Tumors of the Spinal Cord. The Symptoms of Irritation on and Compression of the Spinal Cord and Nerve Roots. Pathology, Symptomatology, Diagnosis and Treatment. By Charles A. Elsberg, M.D. 354 Illustrations. New York: Paul B. Hoeber, Inc., 1925. Pp. 421.

No more logical person could have been selected to write a classic on spinal cord tumors than Dr. Elsberg. In this book he has done all that could be expected. His approach has been most painstaking. Pathology, function, historical approach and differential diagnosis have all been well rounded out and carefully balanced. The material has been carefully compiled from clinical cases and a hundred cases have formed the basis of his material. Much original research work has been incorporated in this volume. The diagrams and illustrations are carefully done and well reproduced. A complete bibliography is appended.

THE DUODENAL TUBE

The Duodenal Tube and Its Possibilities. By Max Einhorn, M.D., Professor of Medicine at the New York Postgraduate Medical School. Second edition, revised and enlarged. Illustrated. Philadelphia: F. A. Davis Company, Publishers, 1926.

In this country, few writers have written more about the duodenal tube than Einhorn, so much so that the instrument and the author are almost instinctively associated. After describing the duodenal tube and its congeners, the analysis of the duodenal contents is discussed, and the diagnostic import of the duodenal tube is emphasized. The duodenal tube may also be used for therapeutic purposes, as for alimentation, the instillation of fluids and gases, lavage and instillation of remedies. It also has a surgical value.

In addition, the author also describes other instruments for the pylorus, duodenum, and small intestine, such as the pyloric dilator, the infantile dilating pyloric catheter, the pyloric dilator and diaphane, the pyloric dilator and aspirator, the double balloon pyloric dilator, the duodenal obturator, the intestinal delineator, the sectional intestinal examiner, the simultaneous gastroduodenal aspirator, the intestinal tube (jointed), and the gastric introducer, together

with the practical use of these new instruments in diagnosis and treatment.

The book is well written and illustrated and is an excellent monograph on duodenal diagnosis and treatment. It is an authoritative treatise that ought to be followed by any one who treats gastrointestinal diseases.

NEURITIS AND NEURALGIA

Neuritis and Neuralgia. By Wilfred Harris, M.D. London and New York: Oxford University Press, 1926. Pp. 418.

Too little is known about these maladies, which are often elusive and baffling. On the whole, the present status of these conditions is far from satisfactory. Some may welcome any attempt to secure additional information in this field, although much familiar ground may be gone over. Harris has based his work on many hundreds of cases, and has also presented some theoretical considerations regarding the taste fibres. The entire body has been covered, with especial emphasis on the facial area. On the whole the author has done a most commendable piece of work.

INFLUENZA

A Treatise on Influenza. With Special Reference to the Pandemic of 1918. By Rajendra Kumar Sen, With a Foreword by Dr. S. R. Harrison, M.R.C.S. (Eng.), L.R.C.P. (Lond.), North Lakhimpur, Assam. Published by the Author, 1923.

This monograph is a compilation of a great deal that has been written on the subject of influenza. Considering that it emanates from India we ought, perhaps, to be charitable in criticism, but it can in no way compare with the treatises on the subject written by European or American authorities. For the American physician it can have no interest.

INFIBULATION

Male Infibulation. By Eric John Dingwall, M.A. London: John Bale, Sons & Danielsson, Ltd., 1925. Pp. 145.

This work represents a comprehensive survey of what little is known of various forms of male infibulation. The author has presented the results of considerable research and the work should prove a valuable reference book for anthropologists, and those who are interested in symbolic sexual manifestations. There is much that is not known of the origin of these practices which may be cleared up in the future.

THE CRYSTALLINE LENS

Semiologie Oculaire. Le Cristallin. Anatomie, Physiologie, Pathologie. Par Felix Terrien. Illustrated. Paris: Masson et Cie, 1926. Pp. 240.

This is a well written monograph on the anatomy, physiology and pathology of the crystalline lens. Excellent illustrations give graphic pictures of its normal and abnormal structure, as well as of its embryological development. It is interesting to have recalled to mind that Descartes was the first to describe the mechanism of accommodation. The author's chapters on the physiology of accommodation and convergence are exceptionally thorough. In the third part of the book he discussed troubles of accommodation, cataracts, traumatic injuries and displacements of the lens. The sections on treatment are sound and conservative. It is regrettable that the bibliography is so scanty.

ECZEMA

Sanitätsrat Dr. Jessner's Dermatologische Vorträge für Praktiker. Heft 14 und 16. Diagnose und Therapie des Ekzems. Von Sanitätsrat Dr. S. Jessner, Königsberg i. Pr. 3. verbesserte Auflage. Leipzig: Verlag von Curt Kabitzsch, 1926. Pp. 173.

This is the third revision of a very practical little monograph on the diagnosis and treatment of eczema, which ought to be very valuable to the general practitioner. The hints on diagnostic and therapeutic points are eminently practical. In the treatment much is made of the usual and reliable drug therapy, both local and general. The newer German drugs are mentioned with their indications. However, irradiation therapy, in the form of röntgenotherapy, radium and mesothorium irradiation, heliotherapy, quartz lamp irradiation, and Finsen light treatment are discussed briefly.

PSYCHOLOGY

The Meaning of Psychology. By C. K. Ogden. New York: Harper and Brothers, 1926.

This is the first book that has come to the attention of the reviewer which is worthy of the title "psychology." It is academic in approach but not tied to tradition. Ogden's findings are sound, simple, valid. He is unafraid, yet unbiased. He favors no school yet selects fearlessly and presents his material in a lucid straightforward manner. The book would be a splendid one as a text in colleges. The physician who desires a working knowledge of modern psychology without struggling through a maze of technicalities can do no better than read this book.

PUBLICATIONS OF THE PATHOLOGICAL INSTITUTE OF THE UNIVERSITY OF HELSINGFORS

Arbeiten aus dem Pathologischen Institut der Universität Helsingfors (Finland). Begründet von Prof. emer. Dr. E. A. Homén. Herausgegeben von Prof. Dr. Axel Wallgren. Neue Folge. Vierter Band, Drittes and viertes Heft. Mit 82 Abbildungen im Text und 7 Tafeln. Jena: Verlag von Gustav Fischer, 1926. Pap. 227-458.

In this number A. Wallgren discusses the eosinophile leucocyte morphologically, morphogenetically and physiologically, as seen in dark field illumination. H. Castrén discusses the structure of the cells of connective tissue tumors in man. J. J. Chydenius writes about the structure of the corpus luteum cells in man and its changes during the menstrual cycle and during pregnancy. These three articles are rather technical histological studies of little value to the general practitioner. Some excellent photomicrographs of the cell structures studied are given.

Of a more practical nature is the article by O. Holsti on the gastrointestinal tract in arthropathies, nephropathies and cardiopathies. This author found that in healthy individuals inflammatory processes are rarely found, whereas phlebopathies are observed even at an early age. In cases of arthropathies, nephropathies and cardiopathies (as also in various other fatally ending diseases) regressive, cirrhotic and inflammatory processes are usually found in the different part of the gastrointestinal tract, although of varying intensity. During the acute phase of these groups of diseases there are relatively marked inflammatory changes, but in the chronic cases the changes are of a various nature even in the same disease, consisting sometimes of regressive processes in the

parenchyma and in increased connective tissue, and sometimes, in addition of inflammatory processes of varying intensity. Sclerosis of the veins is more frequent and not rarely more intensive than normally. Certain arthropathies are encountered more often than in other diseases. The inflammatory lesions in the gastrointestinal tract are usually considered as fresh secondary processes either of the arthropathies, nephropathies and cardiopathies, or of the processes associated with the exacerbations in the upper air passages. Other lesions in the gastrointestinal tract, however, seem to indicate that they are of longer duration and that they have probably preceded both the occurrence of the arthropathies, nephropathies and cardiopathies and their associated processes in the upper air passages. In this respect there seems to be exist a vicious circle.

EPILEPSY

The White Spots of Epilepsy and Other Phases of the Disease. By Edward A. Tracy, M.D. Boston: Richard T. Howard, 1926. Pp. 129.

This is a study of dermatological vasoconstriction in relation to epilepsy as a diagnostic aid and a plea for earlier recognition of epileptic conditions among children.

CONRAD IN THE HOME AND IN THE CONGO

Joseph Conrad as I Knew Him. By Jessie Conrad. London: William Heinemann, Ltd., 1926.
Joseph Conrad in the Congo. By G. Jean Aubry. Boston: Little, Brown & Co., 1926.

In no country of the world is the art of Joseph Conrad Korzeniowski more admired than in America. Therefore two lives of him which have been published recently will no doubt be read more widely in this country than in any country. The first of these is *Joseph Conrad as I Knew Him,* by Jessie Conrad, his widow, and gives the intimate life of this genius.

It strikes one as somewhat ironical that Conrad, who shrank from personal publicity, who was seldom if ever interviewed, who never wrote for the papers or had his photograph taken, and who in a preface to one of his books said that an artist should not appear before the public *en pantouffes,* should be subjected to a scrutiny more personal than many artists have been subjected. But it is human nature a failing it may be, to be curious concerning the most trivial details of the lives of our great men and death generally opens the door to the satisfaction of this legitimate curiosity. Mrs. Conrad, than whom no one can be better fitted to tell of Conrad's private and personal life, does it extremely well. Also it is quite in the proper order of things that Mrs. Conrad, who really knows, should be the narrator, than that a writer perhaps avid of reflected fame should "tickle the palate" of an undiscerning reading public by "yarns" drawn mainly from his own imagination or from hearsay. Such has been the unhappy fate of more than one great writer.

Conrad was not only a genius, with most of the eccentricities of genius, but he was also the victim of bad health. He seems to have inherited the uric acid diathesis, was very dyspeptic, and consequently irritable. He was not only a reserved man but of a highly sensitive and neurotic nature and given to fits of abstraction and nervous excitability. At meal times, even when guests were present, when interested in the conversation, he was addicted to the habit of rolling pieces of bread into pellets with which he bombarded guests, family, and food indiscriminately.

However, it is a book for lovers of Conrad to read as amid its domestic trivialities a remarkable pen picture is presented of the moody, but chivalrous and courteous Polish nobleman and sea captain who gave to the world the most amazingly vivid tastes of the sea and adventure written, on the whole, in the best English ever put to paper in the writing of fiction.

It must be remembered, too, that Conrad was an expert psychologist, his depiction of men and women and their unconscious motives was masterly and this is a reason why his life at home and in the Congo is reviewed in a medical journal. *Joseph Conrad in the Congo* is by G. Jean Aubry, and is a record of an expedition which Conrad made to the Belgian Congo in a French steamer. Conrad himself kept a diary of his Congo experiences, and M. Jean Aubry has taken the trouble to scrutinize and amplify every detail therein with the object of discovering if possible how far actual facts entered into the making of *Heart of Darkness.* There is little doubt, however, that the gruesome sights Conrad witnessed in the Congo had a great effect on him spiritually and mentally while the climate of the tropics undermined his health.

That a man who for twenty years sailed the oceans of the world and saw sights which the sailor sees, should have lived the later years of his life in a secluded village of Kent, where he recreated scenes, people and happenings shows of what mettle he was made. But it is all explained when it is said that he was a genius.

RESEARCH WORK AT THE MAYO CLINIC

The Collected Papers of the Mayo Clinic and Mayo Foundation. Volume XVII, 1925. Philadelphia and London: W. B. Saunders Co., 1926.

As stated in the foreword of the volume, these papers are intended "to suit the needs of the general surgeon and the general physician." This, of course, does not mean that the whole range of medicine has been covered, but it does signify that information, both medical and surgical, most recently subjected to experimental and clinical research at the Mayo Clinic, has been collected and presented in a most instructive and critical manner within a volume of 1078 pages. The subjects presented are amply illustrated and fortified by photographic evidence as well as rigid experimental controls. References to other writers, at times exhaustive, are appropriately appended. Especially striking are the papers dealing with the Hepatic Functions in Health and Disease, by Charles H. Mayo and F. C. Mann, etc., and The Function of the Thyroid Gland, by H. S. Plummer. The diseases of the alimentary tract and urogenital organs are dealt with both from a medical and surgical point of view. Other subjects considered are conditions of the blood and circulatory organs, the chest, the cerebrospinal centres, etc. In the chapter dealing with miscellaneous subjects the specialist will find many things of interest.

The volume is supplied with an ample bibliographic index as well as one of subjects.

Medicoliterary Notes.

The recently issued twenty-third annual report of Bellevue and Allied Hospitals reproduces the architect's proposed plans for a new hospital and grounds.

* * *

Labor and Industry, the publication of the Department of Labor and Industry of Pennsylvania devoted its August issue to describing the Pennsylvania plan for industrial accident reduction.

* * *

Thomas A. Watson, whose antobiography, *Exploring Life*, has just been published by D. Appleton & Company, was the first man ever to hear words spoken over a telephone. He was assisting Alexander Graham Bell in his experiments when he heard the latter's voice utter the words, "Come here, Mr. Watson, I want you." Mr. Bell was in another room and the words came through the apparatus with which the two men had been experimenting.—*N. Y. Times.*

* * *

Prof. Albert Calmette, well known tuberculosis expert, has been instrumental in establishing at Kindia in French Guinea a branch of the Pasteur Institute devoted exclusively to experimental work with monkeys, according to the *Science News Letter*. Families of monkeys are here bred and reared under conditions as much as possible like their native haunts. The experimental work with monkeys in tuberculosis has been especially successful. It had been found that this could not be done in Paris because the monkeys sickened and died in the city atmosphere and surroundings. It is stated that the monkeys at Kindia are not harmed by Calmette's anti-tuberculosis vaccine, and that they do not contract the disease, even when isolated with patients in extreme stages. The immunity lasts more than a year, and can be renewed by fresh dosage.

* * *

A review of our mortality records from June 5th to August 28th of the current year reveals that there are 221 accidental deaths by drowning, according to the New York City Department of Health's *Weekly Bulletin*. "In the last analysis, man is a land animal," says the report, "and when in the water he is out of his medium. More careful patrol of our beaches and shores by police and beach guards would unquestionably help to reduce the number of accidents and it may even be desirable to enact laws forbidding reckless swimming. At any rate, a record of 221 deaths by drowning represents a condition meriting the attention of agencies concerned with the safeguarding of public health."

* * *

A giant salamander thought to be almost 150 years old was recently presented to the Prince Regent of Japan by the head priest of a temple near Asakura, according to press reports. The amphibian is more than four feet long and has been living in a pond in the temple grounds for more than 130 years. This is the first time that an amphibian has been recorded as having had so long a life.

* * *

Public Health Reports for September 17th is devoted especially to the 1925 statistics of notifiable diseases reported throughout that year in the larger cities of the country.

* * *

"Want to be a Physician? Talk it over with 'Doctor Will' Mayo," is the title of an article by Esca G. Rodger in the *American Boy* for October. Much sensible and practical advice and information about the average physician's life and work is given in clear, simple language in the form of an interview with Dr. Mayo of Rochester, Minn.

* * *

Dr. Harold D. Judd of Detroit has recently made a study of one hundred serious automobile casualties, in cooperation with the Detroit police department, and has come to the conclusion that poor minds rather than poor eyes are the cause of most of the accidents. "A man with only 50 per cent. visual efficiency and a 100 per cent. mentality," Dr. Judd is quoted as saying, "would make a more careful driver than the man with perfect eyes and half mentality. Observation has shown also that the man with perfect eyes and full intelligence is liable to be more careless than the man who knows his eyesight is bad, but who is mentally normal." Out of the one hundred cases studied, Dr. Judd found only five unquestionably due to defective eyesight.

* * *

To elaborate this same subject of automobile fatalities—a recent issue of the City Club of New York states—and the figures are confirmed by the reports of the Chief Medical Examiner—that 555 persons, 238 of whom were under fifteen years of age, were killed by motor vehicles on the streets of New York between January 1st and September 1st. During the month of June, fifty-four children were killed in the streets— nearly two a day. The total is a larger number of deaths than were caused by the Florida hurricane.

* * *

Two articles of interest, both most attractively illustrated, in the *Nation's Health* for September are Paintings Provide Ideals for Beauty of Body and Spirit, by Catherine Beach Ely of New York City, and The Dusseldorf Exposition Emphasizes Germany's Health, by Dr. Georg M. Price medical director of the Joint Board of Sanity Control of New York City.

* * *

John Erskine, author of *The Private Life of Helen of Troy*, will take Sir Galahad as his next subject. His book, entitled *Galahad; Enough of His Life to Explain His Reputation*, will be published in November by the Bobbs-Merrill Company.

* * *

Two late publications from the press of Clark University are A Study of Natio-Racial Mental Differences, by Nathaniel D. Mitron Hirsch, and Criminal Intelligence, by Carl Murchison. The latter is a study based upon results of giving psychological tests to seven thousand criminals in penitentiaries of the United States.

* * *

The tomato is the one new salad ingredient added by modern times to the art of the cuisine, according to a recent report of British food experts. The Egyptians used onions and garlic in their salads in large quantities, Confucius liked cucumbers, the Persians used lettuce and radishes, with a sour wine for dressing; and the ancient Chinese mixed with their very elaborate salads mustard, watercress and nasturtium leaves, with hard boiled eggs.

* * *

The World List of Scientific Periodicals Published in the Years 1900-1921, recently issued by the Oxford University Press, contains as a supplementary section a valuable alphabetical list of international congresses and other international organizations, with their various publications.

* * *

The first issue of the *Annales de l'Institut d'Actinologie* has been announced by its publishers to consist of 150 pages, with seventeen original contributions, 140 analyses, and fourteen special plates in addition to those included in the text.

* * *

The Soviet Government has appropriated about $35,000,000 to prevent famines in the Volga district. Attempts are being made on experimental farms to find the best system of crop raising to offset the disadvantages of the irregular rainfall of the region. The average precipitation is only sixteen inches a year—about the same as that in Utah.

* * *

Rejoicing over the lengthening of the average span of life from forty-one to fifty-six years during the last few decades should be tempered by the fact that the death rate in the age group above forty is increasing, according to the *Science News Letter*. Dr. J. Howard Beard, of the University of Illinois, made this statement recently in warning students of the need of better health. "The gain in the expectancy of life is almost entirely due to the saving of lives under thirty-five by the better control of communicable diseases and by infant welfare work," he said. "At the ages of forty-five to fifty, there are four more deaths per thousand than twenty years ago; at fifty to fifty-five, six more; and at fifty-five to sixty, eight more." There is a real danger that the net gain in lives saved from infection will be lost because of the increasing number of fatalities from accidents. Dr. Beard believes. "Whether or not the average length of life shall continue to rise will be determined by how much each person will permit science, education, and religion to influence his habits, control his desires, and direct his action," Dr. Beard added in conclusion.

Abstracts from Current Literature

GENITOURINARY DISORDERS

Diathermy in the Treatment of Prostatic Obstruction.—T. E. Hammond (*British Medical Journal,* January 16, 1926), reports that the application of diathermy is useful in certain cases of prostatic obstruction. It should not be employed in the adenomatous prostate where such good results follow enucleation. It should be reserved for the large and small fibrous prostates and the atrophied prostate. Its application in these cases leads to a better functional result and a lower mortality than after prostatectomy.

So far as the clinical selection of cases suitable for diathermy is concerned, little difficulty will be experienced in the small fibrous and the atrophied prostates. When a rectal examination is performed in the latter, the finger comes up against the posterior wall of the pubis, the hardness of which may lead to the impression that one is dealing with a malignant prostate. The examination carried out with a metal bougie in the urethra enables this error to be avoided. With the large fibrous prostate a careful cystoscopic and rectal examination is essential, and sometimes the differentiation between this and the adenomatous enlargement is by no means easy. The fibrous prostate is somewhat former, and on rectal examination there is not that projection backwards into the rectum, nor on cystoscopic examination into the bladder, which is found with the adenomatous prostate.

Cautery Circumcision.—Isaac G. Duncan (*Urologic and Cutaneous Review,* April, 1926), recommends cautery circumcision in cases of chancre, chancroid and neglected gonorrhea, when accompanied by a redundant prepuce, which are usually complicated by a very severe balanitis or balanoposthitis, preventing the retraction of the foreskin. When due to gonorrhea or an infected chancre, palliative treatment often suffices, but the chancroidal infections not infrequently must have a more radical treatment.

The technic is as follows: The incision is made through healthy tissue under nerve block anesthesia, all of the infected area being cut away even though the skin is left rather short and the mucous membrane is also trimmed off close to the penis, so as to prevent leaving any folds or pockets harboring infection. The entire raw area is gone over lightly with a cautery, with special attention to the margins of the skin and mucous membrane, and if an ulcer be present on the glands penis it also is thoroughly cauterized unless it is situated in or too near the meatus. No sutures or ligatures are used. After the denuded surface has been sponged off with alcohol, it is dressed with an alcoholic solution of picric acid, and after with Ochsner's solution. Healing usually takes place within three or four weeks.

Minor Surgery of Prostate Gland.—M. Stern (*International Journal of Medicine and Surgery,* 39:2), presents a method of relieving prostatic obstructions by partial resection similar to what has been accomplished with the punch method, but which differs from this procedure in many ways and offers a more extensive field of usefulness. To date the results have been good. The method is described as follows: To reduce the problem to a mere cystoscopic procedure permitting of an exact operative technic and the removal of any desired number of sections at a single sitting has been my aim. This in turn resolved itself into two requirements: a, a current possessing certain new qualities, and b, a cystoscopic instrument for its application.

After much technical work and experimentation a cystoscope has been perfected which visualizes unusually large areas of the operative field. It is provided with a small movable ring or loop of tungsten wire which when actuated by a suitable high frequency current is capable of removing, without causing hemorrhage, longitudinal spaghetti like sections of tissue directly under the guidance of the eye and in a water medium. This author named the resectoscope.

The fact that the current employed, besides possessing certain other qualities, can be delivered in a continuous flow through water is the one important feature in making a cystoscopic procedure possible. This current is similar to other high frequency currents heretofore employed for severing tissue, but differs in that, firstly, it will actuate a cutting loop under water and, secondly, it does not arc or jump across a gap. The first of these characteristics makes a cystoscopic procedure feasible and the second eliminates the disadvantages of the socalled fulguration effects. These are irregular sparking and uncontrolled deep penetration resulting in slough formation and possible secondary hemorrhage.

After the instrument has been inserted and a thorough examination with the indirect vision telescope has been made, it is replaced by the working parts containing the direct vision telescope.

The part to be resected is then caused to engage in the fenestrum, which is seen as it bulges rather suddenly into the field and can be felt as a distinct resistance or "hang" to backward or forward motion of the instrument.

The cutting loop is in position just in front of the eye of the telescope and rests against the engaged tissue. The current is then turned on either with a foot switch or by an assistant. Its action is observed in about five seconds by the formation of a small arc or halo around the loop as cell disintegration commences. The loop is then advanced at just the rate of speed necessary to maintain the halo until it has traversed the full length of the fenestrum through the tissue contained therein.

Should the advance of the loop be made at a speed greater than the molecular disintegration of the cells requires, the arc will be lost and the cutting action suspended. This happy peculiarity is due to force and pressure which should not be employed, the passage of the loop through the tissue being entirely due to the disintegration of the cells in its path. Practice in controlling the speed of the cutting thrust should be obtained on pieces of meat in a bowl of water. Experience thus obtained is of extreme importance as it is undesirable to cause desiccation. If a correct technic is employed the cut surface will be but little altered in color.

When the loop rests lightly against the tissue before the cutting thrust begins, a small luminescent ring is seen which, with practice, can be maintained through the entire cut. This is the ideal degree of arc formation, and with it, clean sections of tissue can be removed with no visible charring in the resulting gutter formation and absolutely no hemorrhage. Thus, at a single operation, it is possible to cut as many gutters as may be desired, there being no blood to interfere with clear vision.

Posterior Gonorrhea.—L. L. Michel (*International Journal of Medicine and Surgery,* 39:2), outlines his treatment of posterior gonorrheal infections under two headings, viz., local and general treatment. In the main, the treatment is preventive, and the preventive measures are gentle manipulation, proper drainage, mild solutions of nonastringents used in irrigation, and care not to do too much.

Local treatment.—In every case of posterior gonorrheal urethritis he uses the irrigations of protargol. The earlier these irrigations are used the quicker will the infection be controlled. In the acutely inflamed prostate or vesicle, where protargol is too irritant, the solution is changed to argyrol or neosilvol. In chronic infections of the posterior urethra where instrumentation is necessary, this should be preceded by irrigations of protargol solution. In epididymotomy an incision is made over the inflamed epididymis; the tunica is opened allowing the escape of a turbid serum; the fibrous coat of the epididymis is then incised, using care not to injure the substance. The fibrous coat is now stripped from the epididymis as far as the inflammation extends. A blunt probe is used for any area containing pus or exudates; a turbid serum is usually found. A small rubber dam is placed for drainage and left for about twenty-four hours. The operation is done under local anesthesia by infiltration of the cord and nerve blocking. There is no risk in this operation, and its results are immediate.

General treatment.—1. Hygiene. 2. Sodium iodide: This is used intravenously in patients with a posterior gonorrheal infection if there exists a tumefied inflammation such as one finds in the prostate and epididymis. It does not relieve the pain of an acute prostatitis or epididymitis, but it sometimes causes response in the acute arthritides of gonorrhea. 3. Iron and arsenic: given intravenously as tonic medication, if needed. 4. Vaccines: given immediately, subcutaneously at first, and later intravenously if there is no response to the first method. The autogenous vaccines are essential. Frequent phenomena follow upon the use of non specific proteins with reactions. Pus discharges cease and all evi-

dence of the gonococcus disappear. So much so is this a fact that I take advantage of it in persistent gonococcic infections or when it may be necessary to hurry a cure. Incidentally in women when this treatment is used I have never known the infection to spread beyond the cervix. 5. Heat therapy: gratifying results are obtained by the use of the psychrophore. 6. Diathermy: fine results have been obtained with diathermy. I use it in all posterior infections, in acute epididymitis and the arthritides. I can derive surer relief from its application than from any other form of treatment I know. It is a specific for the pain of acute epididymitis, and preferable to surgical procedures directed toward relief of pain.

Obstructions of the Upper Ureter.—C. H. Peck (*Annals of Surgery,* 83:2) advocates splinting of the ureter as a useful adjunct to operative procedures for the relief of upper ureteral obstruction and early hydronephrosis, especially in the type with hooded pelvis and valvular obstruction at the pelviureteral junction. It is also useful in forms of painful obstruction, without dilated pelvis, usually in conjunction with probe dilatation of ureteral stricture and nephropexy. In pyelitis with obstruction which has resisted conservative treatment, with or without a dilated pelvis, it may aid subsequent drainage enough to save a kidney threatened by damaging infection. The procedure is simple, adds nothing to the operative risk and causes no damage to the ureter if the splint is removed within five or six days.

Catheterization of the Ejaculatory Ducts.—H. C. Rolnick (*Surgery, Gynecology and Obstetrics,* 42:5), feels that catheterization of the ejaculatory ducts is a difficult procedure; most attempts fail. Fluid injected through the ejaculatory duct reaches the seminal vesicle first and not the ampula of the vas. The ampulla of the vas deferens does not communicate directly with the ejaculatory duct, it enters the neck of the seminal vesicle. It is not possible except in a small number of cases to force fluid beyond the seminal vesicle into the ampulla through the ejaculatory duct. Manipulations designed to insert a needle into the vas deferens usually fail and are at best blind maneuvers. Medication of the seminal vesicles through the ejaculatory ducts seldom accomplishes its purpose, for the ampulla of the vas deferens which is always equally involved in the pathological process can be injected in only a limited number of cases.

Kidney Infection.—P. W. Aschner (*American Journal of Surgery,* 40:5), says that in the differential diagnosis the attenuated infections offer the greatest problem and Dr. Beer has suggested the use of staphylococcus vaccine to activate the lesion much as tuberculin is employed for diagnosis. In the very young and in the old the disease may prove fatal because of the development of bacteriemia, embolic phenomena, and peritonitis. The cases complicated by anterenal suppuration and prostatic abscess, and those with diffuse suppurative nephritis are the most dangerous.

The acute cases with frank perinephric suppuration require only incision and drainage of the perinephric abscess. The cases of cortical abscess and carbuncle require not only drainage or excision of the abscessed area but also decapsulation of the kidney so that other foci may be uncovered. If a widespread infection of the parenchyma is found and the septic phenomena are not relieved by conservative procedures, the kidney should be removed, particularly if a bacteriemia persists. Constant watch for metastatic foci must be observed.

Hemostasis in Suprapubic Prostatectomy.—V. C. Hunt (*Annals of Surgery,* 83:2), says that according to his experience the Pilcher bag accomplishes complete hemostasis, as evidenced in most instances by clear urine at all times after operation, and the persistence of clear urine after removal of the bag within twenty-four hours, except in about four per cent. of cases, in which temporary reinflation was necessary. A gauze pack, on the other hand, while usually quite adequate for controlling bleeding, allows a variable amount of blood to ooze into the urine for several days, and often after the pack has occupied the prostatic capsule for several days its removal precipitates bleeding of different amounts, at times to the extent of severe hemorrhage. The bag, in its deflation, simply drops away from the prostatic capsule and has no tendency to precipitate bleeding. Secondary hemorrhage, after the bag had been used, occurred from the fifth to the ninth day in but seven cases, one of which was after partial prostatectomy for carcinoma.

As a result of the early removal of the suprapubic drain, with early institution of drainage of the bladder by urethral catheter, made possible by the Pilcher method of hemostasis, seventy-five per cent. of the wounds healed without suprapubic urinary drainage and they healed earlier. In those cases in which the Pilcher bag was used and the suprapubic tube removed early, healing of the wound occurred on the average in but three fourths the time required when gauze was used to control bleeding and suprapubic drainage was prolonged.

The physical and organic reserve of the patient with prostatic obstruction should be improved by preliminary treatment to insure safety in operating. As Bugbee has stated, removal of the prostate is but an incident. However, it is a most important incident and requires for its successful accomplishment visible procedure when possible and accurate hemostasis.

Studies on the Bacteriology of the Urine in Cooperation with Catheterization of the Ureters.—Robert A. Keilty (*Journal of Laboratory and Clinical Medicine,* April, 1926) report laboratory studies of urine in 162 cases examined by cystoscopy and ureteral catheterization, including bacteriological and microscopic results, as well as a clinical survey of the cases from the diagnostic viewpoint. The cases are divided into three groups, 1, those with clearcut symptoms in which the laboratory merely confirms, as for example, the findings of streptococcus in a ureteral urine where the x ray has already shown a stone; 2, those in which there are symptoms, for example, pus in the urine, where the laboratory makes a diagnosis of Bacillus coli cystitis; 3, those in which there are vague symptoms, and the laboratory findings complete the negative side of the clinical examination, thus eliminating the urinary system. An extensive review of fifty of the cases is made. While the routine use of the cystoscope and ureteral catheter is not advocated, it is suggested that its more frequent use where the urine is studied bacteriologically would clear up an otherwise obscure diagnosis, would eliminate the kidney or bladder as offenders, or would accurately establish a diagnosis strongly suggested clinically.

Focal Infection and Its Relationship to Nonsurgical Disease of the Genitourinary Tract.—Elmer Hess (*Urologic and Cutaneous Review,* January, 1926) asserts that it is beyond any question of doubt that foci of infection, in whatever part of the body located, cause systemic disturbances, and when they do, they should be removed or drained. However, even though an original focus of infection has been the primary cause of the systemic disturbance, its removal does not cure the condition because permanent damage has been done to the part involved. The author believes that the real danger of focal infection is not the socalled rheumatic arthritis, but the constant wearing attack on the cardiovascular renal mechanism and particularly upon the urinary part of the system.

The poisonous material may be either the toxins of the bacteria or the bacteria themselves, and it is the kidneys that must suffer the brunt of any elimination from the blood stream. Normal kidneys very often carry on this elimination unimpaired by the poisons that filter through their parenchyma unless the burden becomes too great. Let the kidney fall below par and the damage starts. The diseases of the urinary apparatus caused by focal infection are: 1, nephritis of all types; 2, pyelitis; 3, ureteritis; 4, prostatitis and seminal vesiculitis. The surgical kidney is left out of consideration here.

If the infection becomes overwhelming in nephritis, the acute hemorrhagic type (streptococcic infections, of which scarlet fever and streptococcic sore throat are striking examples) is encountered, or the process may simply be a degenerative one with gradual destruction of the renal cells (toxic type), or there may be added small petechial abscesses with subsequent scarring of the renal parenchyma and lowering of renal function (staphylococcic infections or mixed infections). In all of these grades and degrees of nephritis, the tonsil, tooth or the sinus is a very likely starting point for the trouble. The treatment is the systematic eradication of all focal infections and the care of all complications.

Pyelitis is the most unrecognizable pathological condition in the body. It is usually complicated by more or less involvement of the renal tubules and ureteritis. It is always infectious but it must also have a local cause, usually obstruction in the urinary tract below the seat of infection

anywhere from the external urinary meatus to the ureteropelvic junction. The infection is usually hematogenous, but it may also be ascending from the lower urinary tract or via the lymphatics. Although the urine may be negative, microscopically it shows pus cells. There may also be normal urinary findings with obstruction of the ureter. The treatment includes removal of the obstruction and institution of drainage and the care of the focal infection. With pyelitis there is almost always also a partial or complete concomitant involvement of the ureteral mucosa, and the treatment is identically the same.

Prostatitis and seminal vesiculitis are usually attributed to a gonococcal infection, and the author believes that the invasion of these organs is very often by organisms that have travelled either by the hematogenous or urinary routes to these organs. These organs often become secondary foci of infection and even though the primary focus (tonsils, teeth, etc.) is cleaned up, the disease entity continues because these secondary foci are cleaned up and very often not suspected. Usually the secondary invader is the organism that causes the systemic disorders.

Concerning Radiotherapy of Prostatic Adenoma.— E. Legueu (*Urologic and Cutaneous Review,* April, 1926) had occasion to operate upon some prostatic patients who had been treated with radiotherapy. The results with x rays were variable but upon the whole they were not favorable, so that operation had to be resorted to. Usually the adenoma remained unmodified after the treatment. The author believes that in one case a cancer of an adenoma developed under the influence of the x rays. He has never seen any happy results from the use of x rays.

The crux of the situation is not whether radiotherapy has an influence upon the adenoma, but whether this treatment is of such a nature as to modify the prostatic disease, to arrest its progress and relieve the retention. The adenoma itself is not of exclusive importance in the genesis of troubles arising from retention. The concomitant alterations of the neck of the bladder play a considerable rôle, and even a predominant rôle in certain cases. And if radiotherapy does reduce the size of the adenoma it can only substitute in its place a hyperplasia of the fibrous tissue—it substitutes a sclerosis for an adenomatous hyperplasia and consequently renders the micturition still more difficult.

This treatment is usually applied for pollakiuria and acute retention, which are minor symptoms and usually subside, but not in chronic retention. It seems that radiotherapy only modifies certain unimportant symptoms accessory to the prostatic disease, but does not change the important symptoms nor even the course of the disease itself.

Until more information is available, the author considers radiotherapy as an insufficient method and at times dangerous, and not easily controlled or uniform. He considers it as an accessory method capable of modifying certain secondary symptoms of the disease, but incapable of modifying the general course, as compared with the curative methods.

Preparation for Prostatectomy.—H. C. Bumpus (*Surgery, Gynecology and Obstetrics,* 42:2) enumerates under this heading four main points: 1, duration and amount of obstruction; 2, indications for and against cystoscopy; 3, care and treatment of associated infection, and 4, restoration of impaired renal function to a point compatible with major surgical measures. Of these the last named presents the most important aspect of the preparation of patients with prostatic hypertrophy, many of whom endure urinary obstruction until the renal function as determined by the phenolsulphonephthalein test has reached the vanishing point and the urea content of the blood has reached over three hundred milligrams for each one hundred cubic centimetres. The establishment of adequate drainage is first undertaken. If the obstruction is complete and acute retention is present, great care must be exercised to empty the bladder gradually. To remove a few ounces at a time is dangerous, as this immediately reduces intravesical tension and so produces edema of the entire urinary tract. Such edema within the renal capsule results in diminished output of urine, and the patient is made worse rather than better. Several methods for the continuous gradual emptying of the bladder are in use, the simplest, and I believe the most satisfactory, being the one described by Van Zwaluwenberg. Usually from three to four days are sufficient for complete emptying. After the bladder is emptied the elimination of the retained toxic substances throughout the body is accomplished by the giving of large amounts of fluid and their elimination by sweating, purgation, and diuresis. A careful record must be kept of the fluid intake and output, a minimal output of two thousand five hundred cubic centimetres being imperative. If this cannot be maintained by the oral administration of fluids, subcutaneous or intravenous administration must be supplemented, preferably the latter, for repeated subpectoral infusions are most trying to the patient and their frequent administration results in costal pain that is most distressing. It has, therefore, been my practice to give one thousand cubic centimetres of physiologic sodium chloride solution daily intravenously until the desired results relative to urinary output are attained.

Following the administration of fluid, the patient is put daily in a hot pack and a profuse sweat induced. No method has proved as free from danger of burns and overheating as the large electric blanket. The patient can be completely wrapped in this and the current turned off as soon as sweating is initiated. Five or ten grains of aspirin, given just prior to the pack, or in refractory cases pilocarpine, is a useful adjunct.

If the patient tolerates a urethral catheter well the preparation may continue with this form of drainage until the urea content of the blood is below forty milligrams for each one hundred cubic centimetres. If the decrease has been slow and the patient's general condition poor with considerable loss of weight and strength, it is safer to perform a cystostomy and permit him to return home for a few weeks or months, as under home environment and food he gains far more rapidly than in the hospital, once adequate drainage has been established. The two stage operation has the advantage of insuring considerable diminution in the size of the prostate, since after the urethra is put at rest, the decrease in edema and engorgement reduces the size of the gland; also the amount of bleeding at the time of operation is much less. However, it compels a blind enucleation, a poor surgical procedure, bound to be followed by a certain number of inferior functional results.

To undertake cystostomy before the urea content of the blood is below one hundred milligrams for each one hundred cubic centimetres is to diminish materially the possibility of the patient's recovery, as so reduced a renal function will frequently not bear the added load imposed by the operation.

Diagnosis by Pyelography.—J. Willan (*British Medical Journal,* March 6, 1926) recalls that the interpretation of the pyelogram depends primarily on understanding that the solid medullary apex of the kidney projects into the outer end of the tube shaped calyx, and that if this tube shaped calyx is distended with fluid such fluid surrounds the solid medullary apex which is projecting into that calyx. If the normal individual calyces are observed they will be seen to have cup shaped outer ends, showing that the sodium iodide has surrounded the normally projecting apex of the solid renal medullary cone.

In pyelonephritis and hydronephrosis there is absorption of the solid apex of the renal pyramids and, consequently, the outer ends of the calyces (instead of being cup shaped as in the normal) are "knobbed". Such rounding is indicative of inflammation and of pyelonephritis with destruction of some portion of the solid renal tissue; an advanced stage of this knobbing is seen in hydronephrosis.

Ptosis of the kidneys is often a part of the picture of general visceroptosis, which can be visualized by a combination of the separate results of pyelography and a barium enema. Kinks and twists in the ureter are common in renal ptosis. Their discovery by pyelography may or may not be of moment; it entirely depends on the presence of cupping or knobbing in the minor calyces. Cupping indicates medical treatment, for there is no back pressure; knobbing means back pressure due to obstruction, and nephropexy may be required to straighten out the ureter and ensure a free onward flow of the urine.

In a congenital cystic kidney there is a general enlargement of the organ, which is shared by the hollow part (pelvis and calyces). The knowledge is used in diagnosing this condition by pyelography. The disease is always bilateral, but one kidney is in a more advanced stage of disease than the other—that is, one is usually larger than the other.

In tuberculosis, the characteristic tendency of tubercle is for it to undergo caseation and distintegration, when the contents are discharged, leaving a cavity. In a disintegrating kidney focus the tuberculosis débris escapes into the nearest

calyx and is voided down the ureter with the urine. Therefore the injected sodium iodide escapes the normal confines of the hollow calyx and "runs amuck" in the solid part of the kidney, producing a blurring in connection with one or more calyces, according to the extent of the tuberculous disintegration.

A hypernephroma usually invades one or other pole of the kidney when it involves at least one main calyx. Depending on the extent of the lesion, the resultant pyelogram may show one or two normal calyces only, while the third main calyx is absent; and the pyelogram has the appearance as if the calyx had been amputated.

Essential (painless) hematuria is occasionally observed. Where the physical signs, apart from the nonpurulent hematuria, are negative, the case may be one of considerable anxiety. Cystoscopy may disclose a normal bladder, also evidence from which kidney the patient is bleeding. Here pyelography helps in the diagnosis. If the urinary tract x ray shadows and pyelogram are normal; if the ureteral catheter end is in the renal pelvis of the affected side and the urine withdrawn contains blood; if the blood pressure is normal; if the urine is free from pus and renal casts; and if the painless hematuria has been of long standing—then the diagnosis of essential hematuria will probably be correct.

A uric acid calculus which may not throw an x ray shadow will sometimes do so after distending the renal pelvis and allowing a part of the opaque solution to drain away; some of the solution may adhere to the calculus and cast a shadow.

Extraureteral shadows can be differentiated by ureterography during pyelography, owing to the presence of some iodide solution in the lumen of the ureter.

The Importance of Pyelography in Urological and Differential Abdominal Diagnosis.—Samuel J. Sinkoe (*Urologic and Cutaneous Review,* March, 1926) states that pyelography is of great practical value in a large number of urological conditions, especially chronic cases, such as stricture of the ureter, pyelitis, pyelonephritis, calculi, kinks and angulations of the ureter, renal tumor, tuberculosis, movable kidneys, bladder pathology, diverticula, prostatic hypertrophy, and tabetic involvement.

Because of the anatomical relationship existing between the urologic and the gastrointestinal tracts, one can easily appreciate the confusion which may arise when the symtoms are referred to the lower right or left abdominal quadrants. Aside from the anatomical relationship which the kidneys and ureters bear to the other important abdominal and pelvic organs, there is a close relationship between their innervation. The nerves which originate from the sympathetic system, are derived from the renal, inferior mesenteric, spermatic, ovarian and hypogastric plexuses. A reciprocal relation has been shown to exist between the innervation of the renal system and the gastrointestinal tract. The renal and spermatic plexuses are directly connected. In addition, connection between the splanchnic nerve and the renal plexus is very distinct onthe left side. Close relationship also exists between the renal and celiac ganglia. As a result of this relationship, one can easily see the problem which confronts one in making an absolute diagnosis, with the signs somewhat misleading, unless one resorts to a urological examination, which should include a pyelogram.

Among other abdominal conditions likely to be confused with lesions of the genitourinary tract, may be mentioned the following: Acute and chronic appendicitis, gastric and duodenal ulcer, cholecystitis, cholelithiasis, etc., postoperative adhesions, abdominal tumors, diseases of the spleen, sigmoid and descending colon, diseases of the liver, inflamed retroperitoneal and mesenteric glands, adhesions from salpingitis, malignancy in the pelvis, tuberculous uterine adnexa, ovarian cyst and pressure upon the ureter by a pregnant uterus. In such conditions as these a complete urological examination is important because of the fact that the genitourinary tract may be entirely at fault, and the referred symptomatology may lead to wrong therapeutic measures. This accounts for original symptoms complained of often recurring following an abdominal operation. For instance, a stricture of the ureter may lead to symptoms that eventually cause unnecessary appendectomies, cholecystectomies, various kidney and pelvic operations, etc. It is also important to remember that in some diseased conditions of abdominal organs, the referred symptomatology may be directed toward the genitourinary tract and other abdominal organs.

Chronic Nephritis.—Malcolm Goodridge (*Medical Clinics of North America,* September, 1925) remarks that since Bright's original classification, the pathological classifications have been legion. Kidneys have been grouped according to their gross and histologic appearance, but, unfortunately, it is difficult to correlate the clinical manifestations of nephritis, on the one hand, and structural changes, on the other. We are not able to predict that a given case of nephritis will furnish at necropsy a kidney with a definite pathological picture, either in terms of its size, its color, or its histology; nor is there any close parallelism between kidney function and kidney structure.

Clinically, one sees two types of renal disease with widespread edema, one with raised blood pressure and one without; and two types of cases with hypertension without generalized edema, one with kidney function more or less impaired and the other with little or no depression of kidney function.

That one should see a case of chronic nephritis with edema and moderate increase in blood pressure at one time, and at some later period should observe this same case free from edema but with marked increase in blood pressure and failing kidney function, in no way changes the value of a simple classification. It is not only possible for one type of chronic nephritis with edema to change to a chronic nephritis with hypertension without edema, and failing kidney function, but it is also possible for a case of hypertension with good kidney function, the benign type of the Volhard and Fahr classification, to terminate in uremia with all the symptoms incident to the terminal stage of the diffuse glomerulonephritis of this classification. This has actually happened in about five per cent of the author's cases.

The variables which occur in the clinical course of chronic nephritis add greatly to the difficulties which surround the proper understanding of the subject, and it must continually be borne in mind that, while pure types of chronic renal disease occur in a large percentage of cases, very puzzling admixtures of types also take place.

It is when one comes to consider prognosis that the importance of recognizing and differentiating clinical types of chronic renal disease is especially emphasized. With very little experience one can predict with some degree of accuracy the immediate and ultimate prospect in a fair number of cases, and one will base his prophecy very largely on a study of kidney function, together with the presence or absence of high blood pressure.

BLOOD AND LYMPH GLANDS

Diagnostic Value of Color of Blood Serum in Pernicious Anemia.—Arthur M. Fishberg (*American Journal of the Medical Sciences,* July, 1926), says that in the active periods of pernicious anemia the blood serum is more highly pigmented than normally, being golden, golden brown, or rarely even dark brown. This is due to an increase in the bilirubin content and to the presence of hematin. In an anemic patient the presence of pale blood serum speaks definitely against the diagnosis of pernicious anemia. Observation of the serum color is of particular value in the differential diagnosis between secondary anemia due to carcinoma and pernicious anemia.

The Reticulated Red Cells: Their Clinical Significance.—William Dameshek (*Boston Medical and Surgical Journal,* April 29, 1926) says that the reticulate count of the red cells is a true index of the amount of bone marrow activity. Before and at the beginning of any remission or permanent rise in red count, the reticulate count surpasses six per cent.; as the culmination of the rise is reached, it gradually falls to normal. With bone marrow aplasia, the reticulate count is extremely low, practically nil. The reticulate count is the best index to bonemarrow activity—better than nucleation of the red cells, polychromatophilia and stippling. There is no better index to prognosis in pernicious anemia than the count of the reticulated cells. Although these are frequently increased, and an elevation up to five per cent. represents probably regeneration going on in the face of greater destruction—a sudden rise in count to above six per cent. presages a coming remission, overbalancing destructive forces. Very grave are the continued low counts that bespeak forthcoming death. The relapse in pernicious anemia is closely related or at least extremely similar to aplastic anemia, which with its evident bonemarrow failure, has an almost absent reticulate count. Platelet

regeneration and aplasia are apparently closely related to red cell growth, for in purpura hemorrhagica the reticulate count goes up before recovery and remains low with impending death from hemorrhages. In the field of diagnosis, the marked reticulosis in congenital hemolytic anemia is a pathognomonic point differentiating that disease from all other anemias with large spleens.

Chloride Metabolism in the Anemias, Especially Pernicious Anemia.—Margaret G. Rioch and A. T. Cameron (*Canadian Medical Association Journal,* March, 1926), adduce evidence that in pernicious anemia not only is there complete gastric achlorhydria, but also that in some, if not all cases the chloride ion is absent from such gastric secretion as may occur. The dependence of the value of whole blood chloride upon the proportion of cells to plasma is emphasized. Determinations of whole blood chlorides are valueless for most clinical purposes. The plasma chloride content is relatively constant and normal in the anemias.

In the active stage of pernicious anemia, especially when the hemolytic changes precede nervous symptoms, there is a slight but undoubted lowering of cell chlorides.

In the remissive stage of pernicious anemia, and in the other anemias studied, the average figure for cell chlorides does not markedly differ from normal, but the extremes show wider variations.

There is in the active stage of pernicious anemia a marked upset in chloride metabolism, characterized by lowering of the blood cell chlorides, and, in some if not all cases, by the absence of the chloride ion (as well as hydrochloric acid) from any gastric secretion that occurs. The former abnormality may disappear in the remission stage. Further work is necessary to determine whether there is definite chloride retention in pernicious anemia.

Chemistry of the Blood.—V. C. Pedersen and M. Exiner (*International Journal of Medicine and Surgery,* 38:11) from the findings of numerous questionnaires sent out to urologists in the United States and Canada, conclude:

Biochemists and chemists have carried to the final degree of development the forms and the technic of tests available for determining the constituents of the blood with the least expense in time, energy, material and cost. Their work might be called the purely laboratory and technical side of the matter.

Urologists are not yet in unanimity as to what shall constitute the primary or basal tests and what the final or supplementary tests. Likewise there is a certain amount of divergence of opinion as to what substances shall be examined for in the incidental or casual patient possibly of the urological type and the special patient definitely of the urinary lesion group. From the foregoing statistics there is relative uniformity in perhaps two thirds of the urological world. It remains, therefore, for the remaining third to so revise their procedures that everyone will understand substantially what is meant by the general term "blood chemistry" as it appears in a record.

From careful reading of the statistics given as to the attitude of the general practicioner and of the general surgeon, it is clear that the application of blood chemistry to their field is still in the creative period. Of course the sooner the general profession adopts the teachings of so important a branch as urology in a matter so indisputable as blood chemistry, the greater will be the service to humanity of the medical profession as a whole and of each special branch.

The Chylomicron (Free Fat) Content of the Blood in Infants.—Louis C. Schroeder and Evelyn Holt (*American Journal of Diseases of Children,* February, 1926) summarize their investigations of the chylomicron content of infants' blood. The study shows that the content is increased in proportion to the fat content of the food. Greater variations in the digestion and absorption of fat seem to take place in infants than in adults. The addition of cod-liver oil usually increases the chylomicron content of the blood, but in one case of rickets such an increase was not found. Oleomargarine caused no marked increase in infants under four months old, nor did ether anesthesia cause a rise. Butter, as added in the butter-meal mixtures, is rapidly digested and absorbed, and these mixtures give the highest chylomicron content in the series studied.

Calcium Content of the Blood in Gout and Arthritis.—Philip Horowitz (*American Journal of the Medical Sciences,* April, 1926), finds that the knowledge of the blood calcium, except in acute gout, whether during the attack or in the interval, is of no help in distinguishing gout from arthritis.

Relation of the Gastrointestinal Tract to Pernicious Anemia.— A. C. Ivy (*Northwest Medicine,* August, 1926) presents evidence which strongly suggests a causal relationship between the gastrointestinal tract and pernicious anaemia, and is sufficient to definitely indicate the administration of hydrochloric acid with and after meals to patients who have a persistent achlorhydria.

GASTROENTEROLOGY

"Surgically Incurable" Gastric Ulcer.—Hans Finsterer (*Wiener klinische Wochenschrift,* March 11, 1926) states that it is generaly well known that gastric ulcer varies in its curability in different individuals, which fact is the basis for the necessity of surgical treatment, as all the operated cases belong to the group of ulcers that are healed with difficulty. The author proposes a classification of gastric and duodenal ulcers according to the grade of their curability:

1. The gastric ulcers that are "curable with internal treatment" include those cases which heal with careful internal treatment.

2. The ulcer that "heals with difficulty with internal treatment" includes those cases which do not heal in spite of repeated internal treatment, and must therefore be treated surgically.

3. The ulcer that "heals with difficulty with surgical treatment" includes those cases which always recur after repeated operations, but which are eventually permanently healed by the avoidance of certain technical errors (especially the Y shaped anastomosis) or by the removal of very large portions of the stomach even after several futile operations. The number of these very rarely recurring peptic ulcers of the jejunum may be considerably diminished if at the time of the first operation a sufficiently extensive resection is done, if, particularly, a sufficient amount of the stomach is extirpated at the radical resection of the peptic ulcer of the jejunum and the Y shaped anastomosis is avoided.

The term "surgically incurable" ulcer should not be used until it has been definitely shown by repeated observations that the truly extensive resection of the stomach was not able to avoid a recurrence, which, as a matter of fact, has not been shown in a single case.

Gallbladder Disease.—J. E. Cannaday (*International Journal of Medicine and Surgery,* 39:2) states that whether to drain or not to drain following cholecystectomy is still a debated point. The number of surgeons, however, who treat the gallbladder on the same general basis as the appendix is increasing. His experience and that of some of his associates covering over three hundred cases, in which the gallbladder has been removed and the incision closed without drainage, have convinced us very thoroughly that it is not necessary to institute drainage after the average cholecystectomy. In some cases, the author has even dispensed with drainage following the removal of an unruptured pus gallbladder. The cystic duct was divided with the cautery and there were not at any time indications of intraperitoneal infection subsequent to the operation.

Many surgeons have argued that inasmuch as bile showed itself in nearly all of the cases in which drainage was used, they leaked and therefore should be drained. In my opinion, the presence of the drain causing foreign body irritation and chemotaxis is responsible for the leakage. Relative to the dangers of leakage after cholecystectomy and the closure of the operation wound without drainage, a slight leakage of bile does not necessarily mean disaster.

Peritonization after cholecystectomy is most important, and while in many cases the parietal peritoneum can be sutured over the raw liver surface, there are cases in which it may be necessary to make use of a portion of the omentum for this purpose. In certain cases of obstruction of the common duct, as an emergency measure at least, it may be expedient to drain the gallbladder into the pyloric end of the stomach or into the duodenum or jejunum. The results are usually quite satisfactory. Again occasionally, it is feasible to anastomose a chronic discharging biliary sinus into the stomach.

There are certain cases in which the surgeon is often in a quandary as to what is the best thing to do. The patient has typical gallbladder symptoms and undergoes operation; nothing is found but a tightly distended gallbladder with a number of apparently old adhesions over its fundus and sides. The author thinks cholecystectomy is advisable in such cases and often gives the desired relief. It is an unfortunate fact that surgical attacks for gallbladder disease do not always bring about a cure.

Hepatitis is present in practically all cases of gallbladder disease in varying degrees. It may be the prelude of liver or portal cirrhosis.

Hepatic insufficiency is the occasional cause of death following gallbladder operations. The patient, twenty-four hours postoperative, develops circulatory failure, has a cold clammy looking skin. Treat with intravenous glucose every four to six hours and give tap water by rectum.

The Classification of the Diarrheas with an Outline of Treatment.—R. D. Rudolf (*Canadan Medical Association Journal,* May, 1926), presents this summary of his address:

Diarrheas may be anatomically classed as high, middle or lower, depending upon the portion of the tract that is at fault. Etiologically considered diarrheas may be classed as nervous, purgative or organic. The treatment of the nervous type consists chiefly of psychic therapy, with the use of nerve sedatives; the treatment of the purgative type of medicinal purgatives to get rid of the irritating contents of the bowel that are the cause of the trouble. The medicinal treatment of the organic forms is likely to be more difficult and consists in the use of protectives and astringents and often of opium in some form. When the condition is in the lowest portion of the tract much of the therapy is best conducted from below. The treatment of mucous colitis is chiefly that of the general nervous condition although local therapy has its place.

Carcinoma of the Stomach with High Blood Eosinophilia.—Emil Weiss (*Journal of Laboratory and Clinical Medicine,* May, 1926) reports a case which is of interest because of the fact that it is the first reported case of carcinoma primary in the stomach with high eosinophilia; there was opportunity to follow the case for a reasonably long time; and experimental work was done in connection with this case. On three different occasions the eosinophiles were 24.2, 25.7 and 31.8 per cent. There have been reports of only six cases of carcinoma with such high eosinophilia. In the author's case no eosinophilia was found in the tumor or surrounding tissue. There was a decrease of eosinophiles after the removal of the tumor, similar to the observations of Vosswinkel and Baradulin, but in a few weeks after the operation there was a rise in the eosinophiles exceeding that before operation; whether this postoperative eosinophilia was caused through metastatic growth of the tumor could not be determined. Neither the tumor extract nor the blood of the patient could produce eosinophilia in guinea pigs, rabbits or dogs. This experimental work does not confirm the assumptions of Kappis, who thinks that the eosinophiles in the blood and in the tissues were caused by the toxins, derived from necrotic tumor tissues. Not the slightest phagocytic properties of the eosinophiles, even in the presence of immune serum, could be detected.

Technic of Appendectomy.—C. R. Robins (*Virginia Medical Monthly,* Februarv. 1926) describes a maneuver which minimizes trauma in removal of the appendix. Trauma increases toxic absorption and by so much reduces the chances of recovery. A McBurney incision is usually made, over the point where the base of the appendix is believed to be. By the use of retractors the base can, as a rule, be exposed. Even if it does not appear immediately it can usually be brought into view by moving the cecum about with a sponge on a stick; upon then describing a quarter circle with the handle of the forceps the appendix is readily delivered out of the wound, provided there are no adhesions. If adhesions exist, they are best separated by working from the base. Usually the maneuver succeeds, but sometimes it is necessary to help the delivery of the appendix, preferably with the small French intestinal forceps, which do not traumatize. The maneuver does away with searching for the appendix with the finger; this sometimes causes considerable trauma, and often fluid is squeezed out of the appendix or a necrotic appendix ruptured. At the base the organ is most likely to be normal or nearly normal, so that a firm hold is secured and the organ may be manipulated without fear of rupture or breaking. The clamp at the base effectually stops further absorption along that channel. The time of operation is shortened, and as evidence of the lack of trauma, post-operative pain and nausea were observed to be greatly diminished.

The Surgical Indications of Inflammatory Diseases of the Gallbladder.—Aime Paul Heineck (*Western Medical Times,* June, 1926) says that cholecystectomy is the indicated operation if the patient's general condition permits:

1. In all localized or diffuse ultraacute inflammatory conditions: Ulcerative, gangrenous, phlegmonous or membranous cholecystitis. In all cases of cholecystitis in which the gallbladder is so altered that judged by gross evidence, "it can not come back."
2. In acute cholecystitis when the gallbladder is very distended from blockage of the cystic duct.
3. In advanced chronic or repeated inflammations of the gallbladder. When the organ is markedly thickened, contracted, atrophied, deformed, shrunken or adherent and when it is evident that it can not be restored to its normal condition, when it is evident that it is irretrievably lost or that the disease is progressive in nature as in fibrous or calcareous degeneration. In these cases, the elasticity of the gallbladder wall is impaired or lost and its glandular secreting apparatus partly or wholly destroyed.
4. In a socalled strawberry gallbladder, the gallblader mucosa being covered with tiny beads.
5. In hydrops fellæ due to blockage of the systic duct, secondary to stricture or to impacted stone.
6. In empyema of the gallbladder due to an impacted stone or strictured cystic duct.
7. For the cure of pathological fistulæ existing between the gallbladder and a hollow viscus, if associated with disturbances, calling for treatment.
8. For penetrating injuries, ruptures and perforations of the gallbladder of either traumatic, calculous or inflammatory origin.
9. For mucous fistulæ of the gallbladder resulting from stricture or other obstruction of the cystic duct.
10. In chronic obstruction of the cystic duct whether due to stone impaction, scar tissue formation or torsion of the gallbladder.
11. In irreparable injuries of the gallbladder.
12. In volvulus of the gallbladder.
13. In benign neoplasms of the gallbladder.
14. In operable malignant neoplasms of the gallbladder.

New Facts Concerning Fat Soluble Vitamines.—Past studies have shown that at least two substances of the fat-soluble vitamine type occur in codliver oil, vitamine A and vitamine D, the former being applied to substance more particularly affecting growth, and the latter referring to the factor playing a part in the deposition of lime in bones. Recently the existence of a third vitamine of the fat soluble class, which plays an extremely important part on reproduction has been proved. This factor, J. C. Drummond (*Lancet,* February 6, 1926) believes to be distinct from either vitamine A or D; it is called vitamine E.

The majority of natural oils and fats, such as codliver oil, consist of about ninety-nine per cent. true fats (glycerides) and some one per cent. substances which resist the action of potash when fats are broken down into glycerol and soap in the ordinary saponification process. This one per cent. is termed the unsaponifiable matter. If this is prepared with care so as to prevent secondary changes, in particular oxidation, it has been found to contain the whole of the vitamines present in the original oil.

The unsaponifiable matter prepared from codliver oil has been submitted to chemical fractionation as follows: Precipitation with digitonin gives rise to cholesterol (inactive) and an active material; when the latter is distilled, there result three inactive substances of varying melting points and an active vitamine fraction together with traces of spinacene. The separation of vitamine A, however, in what can be considered to be the pure condition has not been possible as yet. If an amount of the active fraction weighing only 1/200 mg. be added to a deficient diet, experimental animals have been found to live, maintain health and show a normal rate of growth.

This very highly active fraction consists largely of unsaturated higher alchohols, containing in their molecules only the elements carbon, hydrogen, and oxygen. It is agreed that we must abandon all ideas of the vitamine A

being a labile, ill defined compound, as we at one time imagined, when it is so readily demonstrated that it can survive such a drastic chemical treatment as saponification with boiling alkalies and distillation at temperatures over 200° C.

It has been found that rickets can be cured equally well by exposing the patient to ultraviolet light or by administering a substance such as codliver oil, but the reason for this is still unknown. It was also discovered that a food mixture which, by reason of its deficiency will give rise to rickets in animals, becomes endowed with antirachitic potency after it has been exposed to ultraviolet light. Two possibilities suggested themselves to account for this. On the one hand, it was possible that the treated fats absorbed ultraviolet rays, and that the energy so absorbed was later emitted in the form of secondary radiations, which acted similarly to the direct exposure to the primary radiations. On the other hand, the more attractive hypothesis was that possibly the absorption of the short wave length radiation actually produced in the foodstuffs a substance of the type of antirachitic vitamine D. The precursor of the physiologically active substance was found to be present in the oils or fats. The examination of such activated fats revealed that the conference of antirachitic potency could be traced to the action of ultraviolet light on a constituent or constituents of the unsaponifiable fraction. One of the most commonly occurring substances in these unsaponifiable oils and fats is cholesterol, which is almost universally distributed in living cells.

Cholesterol, or the very closely related compound, phytosterol, is the parent substance of the antirachitic vitamine. If cholesterol is exposed to ultraviolet light under suitable conditions, a product showing an extremely powerful antirachitic action is obtained. This activated cholesterol shows little or no effect on growth nor any other properties of vitamine A, so that it may be definitely accepted that these two substances A and D are distinct.

Carbohydrates in Nondiabetic Acidosis.—A. H. Hoge (*Virginia Medical Monthly,* February, 1926) alludes to nine cases of severe postoperative acidosis—the kind that usually vomit until they die—in eight of which the vomiting was entirely controlled in from twelve to thirty-six hours by the use of glucose and insulin. The ninth case received partial benefit. Three cases of severe toxemia of pregnancy, referred to a hospital by family physicians for interruption of pregnancy, were daily given enemas of sodium bicarbonate, four ounces of a twenty per cent. solution of glucose by rectum every three hours, and five per cent. glucose and insulin intravenously. In each case the vomiting was controlled within forty-eight hours, after which the patients were put on an almost absolute carbohydrate diet, especially fruits and the glucose and insulin continued for one week. The reason for combining insulin with the glucose is that some individuals are otherwise unable to utilize the glucose alone; insulin combined with glucose clears up an acidosis due to ketosis more rapidly than does glucose alone. As for dosage, it is safe to use one unit of insulin to every three grains of glucose. To one thousand mils of five per cent. glucose solution, containing fifty grams of glucose, one can safely add twenty units of insulin and have no fear of shock. Satisfactory results from this form of treatment are obtained only in the type of acidosis due to disturbance of carbohydrate-fat metabolism with the production of ketosis. It cannot influence acidosis of renal origin, due to failure of the kidneys to eliminate acid phosphate. Acidosis in the diarrhea of infancy is partly due to this functional renal incapacity, and while glucose and insulin should be used in such cases they are useless unless a large amount of fluid is also given.

Surgery of Gastric and Duodenal Ulcers.—G. de Takats (*Annals of Surgery,* 83:2) claims several advantages for gastrectomy in the treatment of gastric operations for ulcer and carcinoma, basing his claims on the material of the first surgical clinic of the University of Budapest, from the year 1914 to 1924. During this time both anastomoses and resections were performed, the percentage mortality showing that the latter is by no means a greater risk for the patient than the former. Also in favor of radical procedures was the fact that in examining histologically the resected gastric ulcers, twenty-five per cent. were found to have atypical proliferations on the margin of typical callous ulcers. Macroscopically no expert pathologist can detect a beginning carcinoma developing on the basis of an ulcer.

The operations showed an ever lessening mortality, until the last eighty-eight cases of resection operations gave only a 3.3 per cent. mortality. This the author attributes to three main factors; first, to the use of local anesthesia, plus splanchnic anesthesia when the abdomen has been opened; second, to the use of an intestinal sewing machine, whereby both duodenal and gastric stumps are sewed with powerful crushing clamps that bury new silver clips in four rows and perform an aseptic and watertight closure in two to three minutes; and third, to the constantly growing experience of the staff in this type of operation—the tendency in this country and elsewhere to look down upon technic as something of secondary importance is misleading. A good theoretical basis is extremely important for the surgeon.

The author concludes that while medical treatment aims at rest and neutralization, gastric resection achieves the same. It surely relieves all spasms and lowers the acidity considerably. It has been called mutilating and destructive, but in reality it only creates simpler conditions, while gastrojejunostomy, though surgically a smaller interference upsets the normal function of the stomach.

TUBERCULOSIS

Tuberculosis Immunization.—Nathan Raw (*British Medical Journal,* March 27, 1926) has conducted some experiments on animals which show that it is only possible to protect animals against tuberculosis by using bacilli of human origin against an infecting dose of bovine origin, and vice versa.

The problem of tuberculosis resolves itself into the question of immunity. Contrary to what is observed in other infectious diseases, no immunity is conferred on the human by a previous attack of tuberculosis, which is caused by the same type of bacilli. Pulmonary tuberculosis, which is nearly always caused by bacilli of the human type, does not appear to give immunity in after life, and patients whose disease has been arrested are liable after many years to another acute attack of active tuberculosis. Clinical experience, however, shows that children and young adults who have received a mild infection of bovine bacilli in milk, causing enlarged glands of the neck, bone and joint lesions, and other forms of localized tuberculosis, are practically immune to pulmonary tuberculosis, and it was this observation that led the author to use bovine bacilli to immunize animals and man against the more serious disease of the lungs.

It seems to be probable that children may be protected against infection in the household, but some years must elapse before this can be finally established. All children over the age of one year who are living in the same house with a tuberculous member of the family ought to be protected if possible against infection, and it is in the early years of life that such infection usually occurs. From a long observation of tuberculosis the author is convinced that if some active immunity can with complete safety be given to those children who are directly exposed to infection at home, a long step will have been taken in the direction of prevention. The protection of the community by some scientific method of active immunization is the only effective way to prevent this scourge.

Tuberculosis of Ileocecal Glands.—L. R. Braithwaite (*British Journal of Surgery,* 13:51) offers several suggestions regarding intraabdominal tuberculous conditions:

Those cases in young children where an operation for acute appendicitis shows the source of the trouble to be an acute and possibly a nontuberculous adenitis, and not an obvious appendicitis, are treated by appendicectomy alone. Where a mass of caseous or calcified glands is found, removal of the appendix and closure of the abdomen are indicated, with general treatment to follow. In young children where one or two glands only are seen to be the seat of caseation or calcification, one may consider removal of the diseased glands and of the appendix. One rule should be always borne in mind, i.e., never attempt removal of a diseased gland if it lies close to the mesenteric border of small or large intestine—a fecal fistula may be the result. It would appear to be a dangerous thing to interfere in the way of either curettage of a gland or enucleation of it in the presence of an acute infection as indicated by a high temperature, though the presence of a localized peritonitis

as indicated by a reddening of the overlying peritoneum should be no bar to its extirpation in the absence of severe general symptoms.

Removal of the affected gland or glands is easy so long as the gland is completely calcified or caseated, and so long as calcification has not produced rocky masses which, jutting out, entangle mesenteric bloodvessels. In the latter case enucleation may be very difficult. In a simple case, the left forefinger supporting the gland from behind, an incision is made at right angles to the line of the intestine through the peritoneum overlying the gland, by means of a dissector; the peritoneum is lifted from the front, and, in the case of the small intestine mesentery. from the back of the gland. After removal of the gland and careful ligation of every bleeding point, the peritoneum is closed by a row of Lembert sutures.

It sometimes happens that there is such a mass of inflammatory tissue in and around the capsule of the gland that excision cannot be done without a wide excision of mesentery, endangering the blood supply of the bowel. In these cases one of two things may be done: 1, Opening and curettage of the gland, with careful hemostasis and closure; 2, sequestration of the gland by an omental flap or, better, an omental graft. It should always be borne in mind that the symptoms in the adult variety are due to a localized and probably only a traumatic peritonitis, and therefore a barrier of tissue between the mobile intestines and the irritating focus is all that is necessary.

Whatever local treatment is adopted, it should be followed by heliotherapy.

Tubercle Bacilli in Feces.—That many patients swallow a large proportion of their sputum has long been recognized. This is especially true of women and children, but, owing to the frequent difficulty of diagnosis in children, the importance of obtaining definite evidence of tuberculosis, either by examination of the sputum if it can be obtained, or by other methods, if it cannot, is obvious, and hence any method which will help to this end is of value. The results which have been obtained by examination of the feces of 225 tuberculous children for tubercle bacilli are such as to show that this method is of importance, and should be more widely known and practiced.

All cases admitted to the service of Kathleen A. H. Sykes (*Lancet,* February 6, 1926) either for observation for suspected pulmonary tuberculosis, or with a diagnosis definitely implicating the lung, had their feces examined for tubercle bacilli as a routine. In addition, and as controls, a number of cases of tuberculous peritonitis, cervical adenitis, and children not suffering from tuberculous disease were also investigated. Direct smears from the surface of constipated stools were found unreliable when tubercle are scanty. The antiformin method, though reliable, is protracted. The ligroin method was found reliable and convenient, and is recommended. The technic is the following: A piece of feces the size of a walnut is ground up in a mortar with sufficient saturated solution of sodium chloride to produce an emulsion of the consistency of cream. To this emulsion two c.c. of a mixture of one part of ligroin and two parts of acetic ether are added and the whole intimately mixed, then filtered through three layers of sterile gauze into a clean test tube and allowed to stand for twenty minutes. With a sterile pipette a few drops of the layer immediately beneath the ligroin acetic ether layer are withdrawn, expressed on to a slide, spread and fixed by heat.

Evidence is submitted to show that there is little doubt that the acid fast bacilli found in the feces of children suffering from pulmonary tuberculosis are tubercle bacilli. Nonpathogenic acid fast and alcohol fast bacilli are not found in human feces, and tubercle bacilli are not found in the feces of healthy individuals. Tubercle bacilli, if present in the sputum, can be demonstrated in the feces in 100 per cent. of cases. In no case in which the sputum on repeated examination was negative for tubercle bacilli were these bacilli found in the feces. In children suffering from pulmonary tuberculosis tubercle bacilli can frequently be found in the feces when no sputum can be obtained for examination. The presence of tubercle bacilli in the feces is not necessarily evidence of an intestinal lesion. In children, who so frequently swallow their sputum, the examination of the feces for tubercle bacilli can be more generally applied than the sputum examination, and yields a higher percentage of positive results. It is in consequence of definite value in diagnosis and prognosis.

Studies on Nutrition in Tuberculosis.—In a study of experimental tuberculous infection in the albino rat and the influence of vitamine deficient diets thereon, Maurice I. Smith, and E. G. Hendrick (*The Journal of Laboratory and Clinical Medicine,* May, 1926) chose the rat in an attempt to break down the natural resistance of this animal to tubercle infection by depriving it of some of the dietary accessories which are known to be so vital in its nutrition and metabolism. A virulent human strain of tubercle bacilli, H37 was used to produce the tuberculous infection. The albino rat so infected can be rendered susceptible to tuberculin shock by withholding fat soluble vitamine A from its diet. The experiments described indicate that the tubercle infected rat deteriorates more rapidly than the noninfected control when maintained on a diet of low biological value and low in fat soluble vitamine A. Liberal allowance of fat soluble A appears to afford protection against the early deterioration. It is not certain whether this indicates an increased demand for vitamine A. The increased susceptibility to tuberculin shock of the infected vitamine A deficient rat appears to offer evidence in favor of the former view.

Retroperitoneal Tuberculosis Lymphadenitis.—I. S. Radvin (*Annals of Surgery,* 83:6) describes two cases, in both of which the patients did well under good hygiene and x ray treatment. In his opinion, it is likely that in the early stages good hygiene alone will cause subsidence and cure. In all cases it is important to increase the normal vital resisting forces of the body. Removal of the nodes in those cases where this is feasible should be done, but it is unwise to subject the patient to the risk entailed when the blood supply to the viscera is liable to be compromised.

It is important to do a biopsy in any case where doubt exists since the x ray treatment for retroperitoneal sarcoma is different from that of retroperitoneal tuberculosis. In the first instance the dosage is intensive, while in the latter it is mild, and intensive x ray treatment in the cases of retroperitoneal tuberculosis will not give favorable results.

Primary Tuberculosis of Gallbladder.—F. W. Rankin and F. M. Massie (*Annals of Surgery,* 83:6) report on a small series of cases of which they say:

The treatment of tuberculosis of the gallbladder must of necessity be decided by the case. Acute miliary tuberculosis need not be considered. In conditions secondary to far advanced active tuberculosis elsewhere, the surgical treatment of the gallbladder should be palliative. In those cases where local and general conditions permit, we feel that a cholecystectomy should be done, but in saying this we are not unmindful of the figures in this short series, including our own case; namely, that of four cholecystostomies, there were four recoveries, two without fistula, while of four cholecystectomies done there were but two recoveries.

Surgery on the Tuberculous Patient.—F. W. Griffith (*Surgery, Gynecology and Obstetrics,* 42:6) states that local anesthesia should be used whenever possible. Ether does practically no more harm to the tuberculous than to the nontuberculous lung and a general anesthesia with ether should be employed whenever the necessity arises. Ethylene bids fair to replace ether in these cases.

Pulmonary tuberculosis is not a strong contraindication to surgery. On the contrary, many patients are greatly benefited by the surgical removal of conditions which are indirectly retarding their recovery.

Whenever a tuberculous patient becomes pregnant intervention should be considered. If it is deemed wise to allow the pregnancy to go to full term, well and good; if, however, it is reasonably certain that intervention will have to be done it should be done early before irreparable damage has been done to the lungs.

Tuberculosis of Mesenteric Lymph Glands.—J. R. Head (*Annals of Surgery,* 83:5) reports a case of rupture of a caseocalcareous tuberculous gland of the mesentery and surveys the literature, summarizing his deductions as follows:

In Floderus's series two thirds of the cases occurred between the fifth and tenth years. It may occur in infants and is not uncommon in youths and adults. The serious complications, especially ileus and perforation, are more likely to occur in the older patients. The mode of infection is ingestion and the route is through the intestinal mucous membrane to the glands that drain it. In a majority of cases the bacilli are of the bovine type. The pathology is that of tuberculosis in glands in other locations. In general there

are two types—the diffuse and the localized. Many of the symptoms and complications are secondary to periadenitis and adhesions or to chronic or acute perforation of purulent or caseous glands. These may be secondarily infected.

While certain syndromes are more common than others, the disease is characterized by the diversity of its clinical manifestations. There may be no symptoms, the picture may be one of chronic abdominal pain, with or without acute exacerbations. The first symptoms may be acute, due either to an exacerbation of a latent process or to one of the complications.

The physical findings are as follows: There may be poor nourishment and development, but as often as not the patients are in good physical condition. There may be another tuberculous focus in this body. In most instances there is an abdominal tumor. This may be located in any part of the abdomen. In a majority it is in the right lower quadrant. During the acute exacerbations there is a tenderness and spasm. The stools may be foul, copious, shiny and rich in fat.

Ileus, abscess formation, chronic or acute perforation, and pressure upon the duodenum, the common bile duct, the ureter, or the portal vein, and miliary tuberculosis are the chief serious complications. The diagnosis is difficult and is rarely made prior to operation. The condition most often simulated is chronic or acute appendicitis, but the symptoms may suggest almost any abdominal condition. The x ray will show calcification if present and in children a positive von Pirquet reaction is of value.

The treatment is medical and surgical. The former is the same as for surgical tuberculosis in the other regions. The operative procedure indicated will be determined by the stage of process. Extirpation of glands where possible. Extirpation of glands and resection of the bowel where injury to the mesenteric arteries is unavoidable or where there is gangrene. Drainages of abscesses. Opening and curettage of caseocalcareous masses with subsequent packing or infolding suture.

Phrenic Evulsion as an Aid in the Treatment of Pulmonary Tuberculosis and Bronchiectasis.—H. Morriston Davies (*British Medical Journal,* February 20, 1926) states that when the phrenic nerve is paralyzed by severance of the nerve supply, there is a two fold effect: the diaphragm cannot pull on the lung and expand the lower lobe and it produces a partial collapse of the base of the lung. As a result, benefit is derived from the diminution in the outpouring of toxins into the lymph stream.

The indications for phrenic evulsion are the following: 1, As a means of arresting disease in cases of basal tuberculosis and bronchiectasis; 2, in association with local thoracoplasty it is applicable in the conditions described above in which the disease is quite extensive; 3, to assist in controlling the disease in more generally extensive or more advanced or more acute cases of pulmonary tuberculosis; 4, as an accessory to artificial pneumothorax treatment; 5, for the treatment of symptoms; 6, as a preliminary to thoracoplasty: a, as a test of the ability of the sounder lung to stand up to increased work which will be imposed on it by the major operation; b, as an aid in improving the general condition of the patient, and c, to prevent the development of catarrhal signs in the lower lobe; 7, as a preliminary to radical treatment of a tuberculous empyema; 8, after imperfect resolution of pneumonia, and 9, in order to free the heart from embarrassment.

The technic is as follows: The operation is done under local analgesia. Novocaine, one per cent., is used with adrenaline hydrochloride; twelve c.c. should be sufficient to anesthetize completely the field of operation. An injection of omnopon, one third grain, or morphine, one fourth grain, is also given. The skin incision is either oblique along the lateral border of the sternomastoid muscle, five cm. long, the centre being five or six cm. above the clavicle; or transverse, five to six cm. above the clavicle, two thirds being lateral and one third mesial to the lateral border of the sternomastoid muscle. The skin, platysma, and fascia are divided and the lateral border of the sternomastoid is defined and exposed, and is then retracted mesially. The next landmark is the omohyoid muscle crossing the wound downwards and laterally. This is retracted downwards. The scalenus anticus muscle with the phrenic nerve crossing it is still concealed from view by fat, glands, and the deep cervical fascia. The dissection must be carried down through these and the muscle exposed. If the nerve is running a normal course it will now be seen crossing obliquely from above downwards and mesially across the surface of the muscle. Care must be taken not to displace the nerve to one side with the fascia. During the deeper dissection the internal jugular vein will be seen on the mesial aspect of the wound, and must be drawn to one side. The superficial cervical and supraclavicular vessels can be seen running across the lower end of the wound.

The course of the phrenic nerve is not constant; it may not come on to the anterior surface of the scalenus anticus till low down in the neck; it may cross to the mesial margin high up; at times it may run through the substance of the muscle. When the nerve is pinched with a forceps the commonest sensation is one of pain referred to the shoulder or to the upper part of the arm. Sometimes a fluttering sensation is felt in the region of the costal margin, or a definite sharp contraction of the dome of the diaphragm can be both seen and felt.

The nerve is divided at the highest exposed point, and the cut peripheral end is seized in a forceps. Traction is now applied, and as each successive length of nerve appears a Spencer Wells forceps is applied to it, so as to retain a hold on the nerve should it rupture immediately below the upper forceps through which the traction force is exerted. When some 10 cm. of the nerve has been slowly drawn out from the wound, an extra pull will probably rupture the filaments from the diaphragm and the whole nerve comes away. At the moment when the break occurs the patient usually experiences a sudden jerk at the base of the chest. The operation is now concluded by stitching together the divided deep facsia, the superficial fascia and the platysma, and the skin.

Sanocrysin in Pulmonary Tuberculosis.—R. Staehelin (*Schweizerische Medizinishe Wochenschrift,* March 3, 1926), reports that experiments with sanocrysin (sodium gold thiosulphate) showed that *in vitro* this substance inhibits the development of tubercle bacilli in a concentration of 1 to 100,000 and with a concentration of 1 to 1,000,000 there is marked inhibition; it makes the entrance of metallic ions into the bacilli possible by destroying their lipoid membrane, and in doses that are nontoxic for normal animals it kills tuberculous animals under the picture of a tuberculin shock. The conclusion was therefore drawn that it destroys the tubercle bacilli in the living organism, at the same time liberating the toxins and producing a shock in hypersensitive animals. If the resulting toxins could be neutralized, a *sterilisatio magna* ought to be possible. Experimentally this has been shown to be possible.

Just as with tuberculin, there is a focal and general reaction. The focal reactions take the form of severe dyspnea and cyanosis and râles. The general reaction appears as fever appearing two to three hours after the injection, returning to subnormal the next morning. Here there is serious danger of a fatal collapse and only intravenous injections of serum may save the patient. Subsequent injections do not result in fever or only a slight fever appears. The rise in temperature may be only slight or entirely absent. Another cause of death is often a cachexia. Marked losses in weight are quite common, but the patient feels unusually well with all that. On cessation of the treatment the loss in weight is rapidly recovered. In a few cases the loss in weight may be associated with a marked loss of strength and the patient may die from exhaustion. There may also be albuminuria, sometimes quite severe and of long duration, but never as the result of a severe renal injury. Toxic exanthemata also appear and should be considered as a warning signal, but these do not recur if no injection is again given until the rash disappears entirely. Vomiting, occurring immediately after an injection is harmless. Singultus is also a warning signal, but usually disappears rapidly. Diarrheas, occasionally occurring pains in the chest or slight dyspnea, the increase of a pleuritic exudate or increased abdominal pains with peritonitis, and, perhaps, certain ocular symptoms should be considered as focal reactions. They are all insignificant as compared with shock, febrile intoxication and cachexia.

The cases studied show that the results with sanocrysin are such as have never been observed heretofore. With a careful technic, the dangers are not really serious. Certain conditions, however, must be fulfilled, namely, careful temperature measurements so that the injections should not be given at too rapid a succession and thus in time treat a sudden fall of temperature with injections of serum and stimu-

lants. The urine should be examined regularly for albumin, especially immediately after an injection. The patient should be kept in bed during the entire course of treatment.

The doses are as follows: In afebrile or subfebrile cases, begin with 0.5 c.c., followed after three days by 0.75 or 1.0 c.c., then 1.0 c.c. every week (in small women only 0.75 c.c.). With a rise in temperature, albuminuria, or other complications, the next injection should not be given until the symptoms have disappeared. In febrile cases no more than 0.5 c.c. should be given; in acute febrile cases begin with 0.01 to 0.025 c.c. Smaller doses should be avoided as the remedy apparently possesses only a slight therapeutic breadth, which does not lie between a highly dangerous and a low ineffective zone, which may also be dangerous. In collapse, give intravenous injections of antituberculosis serum (necessary only with this emergency, otherwise not) and stimulants. Sanocrysin should not be given simultaneously with arsenic. After seven to nine injections the treatment should be temporarily stopped and may be repeated after several months.

Treatment of Phthisis with Sanocrysin.—Knud Faber (*Lancet,* July 11, 1925), formulates the following preliminary conclusions about the sanocrysin treatment from our present knowledge:

1. Sanocrysin has a specific curative action on tuberculosis of the lungs.
2. It does not seem to have the same effect on extrathoracic localized tuberculosis (surgical tuberculosis, meningitis, etc.).
3. It is very effective on fresh tuberculosis of the lungs that has been manifest less than one year.
4. In older cases the effect of the treatment is uncertain.
5. It is difficult to use it in febrile cases, but some good results may be obtained in old cases of apyretic fibrous phthisis. So far it has not been able to cure acute lobar tuberculous pneumonia.
6. In ordinary cases a treatment lasts three to four months.
7. Generally the dangers may be avoided when the treatment is carried out in the right manner and with caution.
8. The antitoxic serum has a curative effect on acute shock. Its effect in preventing albuminuria is not clear, and further investigations are necessary.

Treatment of Pulmonary Tuberculosis with Sanocrysin.—The favorable results reported with the use of sanocrysin and its complementary antituberculin serum in experimental tuberculosis in cattle have urged T. R. Elliott (*Lancet,* January 16, 1926) to try them in the human being.

Sanocrysin is a very soluble thiosulphate of sodium and gold, containing forty per cent. by weight of the latter metal. It is given intravenously as a solution in ten c.c. of water, and care is needed to prevent the needle from leaving an indelible black spot in the skin. For the first few days after an injection gold can be detected in the urine easily, and to a less amount in the feces. It has been found that only thirty per cent. is so excreted; the rest stayed indefinitely in the body. The gold tends to accumulate in the kidneys.

The obvious clinical results of administering the drug, in a dose of 0.5 gm. followed three or four days later by 1.0 gm. are as follows: There is generally a little nausea, and the patient may vomit once or twice in the first few hours. Some complain of a persistent metallic taste in the mouth with dislike for food. There may be a slight headache. That is all, except in patients with active and well-vascularized tuberculous infections. In these the temperature rises; there is often an intense and widespread rash, scarlatiniform or morbilliform; there may be albuminuria with renal casts, but never any edema or serious diminution of urine. The general reaction is not one of severe discomfort. But if the drug is pushed unduly there may suddenly develop alarming features, either of hyperpyrexia or of socalled shock with fall of temperature, a rapid and weak pulse, hurried breathing, and general collapse. Also, excessive doses may lead to intense albuminuria, to persistent vomiting or diarrhea, with complete distaste for food and rapid loss of weight. Most of these features have been ascribed to the liberation of tubercle toxins from bacilli killed by the sanocrysin, and to combat them a special antituberculin serum was prepared. But whichever be the cause, whether the tubercle toxins or the ill effects on the tissues of an excessive concentration of the gold salt, there is very real danger in an ill regulated use of sanocrysin. There may be sudden or progressive exaggeration of the more serious symptoms of the tuberculous infection, or there may be a poisoning of the kidney, of the liver, and even of the skin, with a drug dermatitis that is quite distinct from the relatively transient rash.

Only eleven cases were treated. The author believes that the treatment has not done harm in any case so treated. The sanocrysin seems to have a specific action on tissues infected by tuberculosis. This is suggested by an unusually inflammatory vascularization of the tuberculous areas in two cases examined postmortem. In other pulmonary cases which did not die there was evidence of a focal reaction in some pain in the chest, slight dyspnea, and often an increase for a while of adventitious auscultatory sounds. There was no proof of the tubercle bacilli being killed directly by the gold salt; but the inflammatory reaction in the tuberculous areas was attended by the escape into the circulation of toxins which produced general bodily reactions similar to those caused by large injections of tuberculin. Such general reactions were seen only in patients with active and well vascularized tuberculous lesions. In cases of tuberculous cervical glands and tuberculous fistula from the shoulder joint there was no reaction and no benefit.

The best results are seen in patients who react at first with sharp fever and rash. The next injection must then be delayed for a week after the fever reaction or even much longer so as to ensure that the following reaction shall be of less severe character. If the injections are spaced widely enough dangerous reactions and loss of weight can be avoided.

Tuberculous Adenitis Treated by Radium.—Philip Gosse (*Lancet,* April 24, 1926) obtained the following results in the treatment of fifty consecutive cases of tuberculous adenitis with radium: thirty-seven cures, nine improvements, three cases unimproved, and one death. These statistics give a very good idea of the results to be expected from such treatment.

The technic itself is simple. The glands to be treated, having been carefully located and palpated, are marked out on the overlying skin with a dermographic pencil. Over these localities "half strength" plates, i.e., plates covered by 2.5 mg. radium element to each square centimeter of surface, and covered by a sheet of Monel metal 0.3 mm. in thickness and screened with silver 1 mm. in thickness, are applied, and held in place by pieces of adhesive plaster, covered by a few turns of a bandage.

The action of the radium on the tuberculous glands is the following: There is an ultimate fibrosis and an early disappearance of lymphocytes, which either disintegrate or are phagocytosed by macrophages. The lymphoid myeloblasts, except after large doses of radiation, do not perish, and later may reform lymphocytes. The lymphoid follicles atrophy, only the central cells remain. The endothelial meshwork of the gland remains little altered, except for a great increase of fibrous tissue, so that the whole gland, shrunken from the loss of lymphocytes and other cells, comes to consist of narrow spaces lined by endothelial cells running through thick fibrous tissue. In this tissue the tubercles persist, more especially the giant cells, and here tubercle bacilli have been found persisting many months after radiation. It has been concluded from these appearances that the good clinical results are due to the creation of a site unfavorable to the growth of the tubercle bacillus, rather than to any direct action of the radiation on the bacillus. The dose of radiation given is always very much less than the lethal dose for the bacillus; nevertheless, a direct action on the bacillus may also be a factor.

Diagnosis of Clinical Hilum Tuberculosis.—John B. Hawes, 2nd (*Boston Medical and Surgical Journal,* January 21, 1926) says that there are many instances where a positive diagnosis one way or the other is impossible and where we must simply play safe and build up the child. But he finds the following of help to him.

For a positive diagnosis: exposure, real malnutrition and real underweight, ease of tire, being tired all the time, and temperamental changes. Of importance but not essential to a diagnosis are a positive Von Pirquet reaction, and x ray evidence of marked hilum changes.

For a negative diagnosis, presence of tonsils, adenoids, etc. that can account for symptoms, apparent but not real underweight, negative Von Pirquet repeated in absence of factors that would tend to make it negative, and absence of ease of tire and fatigue.

Medicolegal Notes.

HYPERSUSCEPTIBILITY TO NOVOCAINE NOT A DISEASE

The Circuit Court of Appeals, Fourth Circuit, holds, Mutual Life Ins. Co. of New York v. Dodge, 11 F. (2d) 486, that death resulting from the local administration of novocaine preliminary to an operation for the removal of tonsils, because of the patient's hypersusceptibility to that drug, was a death by "accidental means" within a clause in an accident insurance policy covering death directly from bodily injury. Experts testified that the supersusceptibility was not an infirmity but a peculiarity, and was not covered by the exception in the policy of death "from bodily or mental infirmity or disease of any sort," "infirmity" and "disease" being considered practically synonymous, and to refer only to an ailment or disease of a settled character.

STATEMENTS TO DIAGNOSING PHYSICIAN WAIVED IN POLICY

A life policy provided that it should not be effective unless the applicant had not consulted or been treated by a physician since his medical examination. The fact was that he had not only been treated, but that a serious operation had been performed. The policy also waived all provisions of law forbidding physicians who had attended or examined him to disclose information thereby acquired. In a suit for cancellation and rescission of the policy for fraud, the federal district court for New Jersey holds, New York Life Ins. Co. v. Renault, 11 F (2d) 281, that fraud in the procurement of the policy was shown, and that statements made by the insured to his physician for the purpose of guidance in diagnosis and treatment of disease were clearly admissible in evidence. The privilege was expressly waived, and failure to receive the physician's testimony would result in fraud.

LACK OF CAUSAL CONNECTION BETWEEN ACCIDENT AND INJURY

In an action for injuries alleged to have been sustained when a street car ran off the track and collided with an automobile, which in turn struck the plaintiff, the Alabama Supreme Court, Columbus Electric & Power Co. v. Downs, 106 So. 593, was of opinion that there was no causal connection between the accident complained of and the loss of plaintiff's right leg, which was amputated about ten days later, and which was the principal item of damage complained of. The leg appeared to have been amputated on account of a varicose ulceration of long standing, incurable and dangerous to life. The surgeon who performed the operation testified that it was done on his suggestion, and that the injuries received by plaintiff in the accident were superficial scratches, which contributed nothing to the necessity for an amputation. Judgment for plaintiff was reversed and the case remanded.

EVIDENCE AS TO EFFECT OF AUTOMOBILE ACCIDENT

In an action for personal injuries resulting from a collision between the plaintiff and the defendant's automobile the Wisconsin Supreme Court, Gerber v. Wloszczynski, 206 N. W. 206, said that the fact that an enlargement of the heart was not detected until two and one half years after the accident raised a doubt as to whether it resulted from the accident. The testimony of a physician that he believed it quite possible that the mitral regurgitation and enlarged heart then first observed resulted from infection was held not to be opinion evidence based upon a reasonable certainty. It was held that, on a new trial, granted because of excessive damages, the opinion of a medical expert witness for the defendant that the regurgitation and enlarged heart resulted from congenital malformation would make it incumbent to meet it with an effective rebuttal.

MALPRACTICE IN LEAVING CLIPS ATTACHED TO CERVIX OF WOMB

A surgeon performed a vaginal operation on the plaintiff. Two metal clips used as sutures were left in the neck of the womb, where they remained for more than three years, causing pain and hemorrhages. Upon their removal plaintiff's trouble ceased. The Minnesota Supreme Court, Fowler v. Scheldrup, 207 N. W. 177, held that the evidence was sufficient to justify the jury in finding that the defendant inserted the clips and failed to remove them and that the presence of the clips was the proximate cause of plaintiff's trouble.

ALLOWANCE OF EXPENSES FOR FUTURE MEDICAL ATTENTION

The question of whether expenses for future medical attention should be allowed in a personal injury action was held properly submitted to the jury where it appeared that the plaintiff had only light perception in his left eye, that the retina was detached on one side, that this condition was permanent, and that at the time of the trial whenever plaintiff became warm at his work he felt a severe pain in his left eye, and his right eye would flood up so that he could not see with it for some time. Halley v. Federal Truck Co. (Mo. App.), 274 S. W. 507.

PERSONAL INJURY ACTION

In a personal injury action by a married woman it was held error to include bills for medical attention and hospital services which had been paid by plaintiff's husband, since the Missouri Married Woman's Act, which authorizes her to contract as a feme sole and makes her separate earnings her own property, does not change the commonlaw rule by which the husband is primarily liable for the support of his wife, which includes medical attention and hospital services. Had plaintiff paid the bills, she could have recovered for them in the action. In the absence of a showing that she did so, the right to recover therefor was in her husband. Irwin v. McDougal (Mo. App.), 274 S. W. 923.

COMPETENCY OF MEDICAL MAN AS WITNESS IN MISBRANDING CASES

If it appears, in a misbranding proceeding, from the testimony of a witness on preliminary examination, that he is learned in the science of chemistry, or has been regularly and legally admitted to the practice of medicine, and that he has knowledge of the drug elements contained in articles transported in interstate commerce and their efficacy or lack of efficacy as curative agents, used either separately or in combination in the treatment of the diseases specified on the label, his opinion on that subject is competent evidence regardless of whether he has had actual experience or observation of the effect of the use of such drugs in the exact form in which they are transported in interstate commerce. The weight of his evidence is a question for the jury. Goodwin v. United States, 2 F (2d) 200.

SALE OF JAMAICA GINGER TO BE USED AS EVIDENCE

The Circuit Court of Appeals, Sixth Circuit, holds, Sherman v. United States, 10 F. (2d) 17, that under section 4 of Title 2, National Prohibition Act, forbidding the sale of medicinal preparations "for beverage purposes, or under circumstances from which the seller might reasonably deduce the intention of the purchaser to use them for such purposes," there is no violation of law in which the seller can participate, either by direct purpose or by equivalent indifference and negligence, unless the purchaser at the time of the purchase intends beverage use; and a sale of Jamaica ginger to a person who intended to turn it over to an officer for use as evidence did not sustain a conviction of the seller.

The Present Status of Our Knowledge Concerning the Thymus Gland

I. A. ABT, M.D.
Chicago

The thymus is an organ which has great interest for the anatomist, physiologist, and morphologist, though none are more vitally concerned than the practitioner and specialist in pathology of childhood. It is of striking significance that this organ occurs in the higher vertebrates, reaches its maximum size during early life, and undergoes retrogressive changes at maturity. One would assume *a priori* that this organ must have some relation to the functions of growth and development. In spite of the immense amount of energy and labor which have been directed toward the solution of the problems concerned in the anatomy and physiology of the thymus, there has been no uniform agreement by the various investigators.

HISTOGENESIS

There is still considerable uncertainty concerning the origin of the thymus and the discussion goes on. The consensus of opinion, however, favors the view that the thymus is an epithelial organ that eventually becomes infiltrated with lymphocytes. This has been referred to as the infiltration or immigration theory.

The epithelial components in various mammals are of diverse origin; in some they are ectodermal, in some entodermal and in others they are combined ectoentodermal. In man the lymphocytic infiltration is supposed to begin during the second month of intrauterine life.

Hammar (1) believes that the thymus is not a transitory organ but that it persists more or less throughout life. At puberty its parenchyma begins to be reduced in size, and this process is known as age involution.

The organ increases in size from infancy up to the period of age involution. After this time a rapid reduction in the bulk of the parenchyma of the organ occurs, which together with the interstitial connective tissue is replaced by adipose tissue which forms the greater part of the organ at this period.

At age involution the cortex of the gland is first diminished in size. A little later on the medulla undergoes reduction, and still later the number of Hassall's corpuscles begins to diminish; and this diminution continues.

The nature of the involution as is shown by histological study consists of simple atrophy. The individual structure of the gland continues though it is smaller and there is diminution in the number of cells. In an atrophied thymus, one still finds remnants of cortex, medulla, reticulum and Hassall's corpuscles.

FUNCTION

The function of the thymus gland remains a question in physiological speculation. It has already been pointed out that the nature of the cellular elements and their source of origin has been a matter of controversy. As has been said, the thymus in the first stage of its development is an epithelial structure, but in its growth it becomes transformed into a structure resembling a large lymph gland, containing many lymphocytic cells.

While some believe that these cells are true lymphocytes derived from the mesoderm, and that they have migrated into and replaced the epithelial tissue, others believe that they are epithelial in origin; possibly arising from repeated division of the original epithelium and remaining epithelial to the end. Any view concerning the function of the thymus must depend on the view adopted concerning its structure.

Stewart (2) in an excellent résumé points out that if the thymus in its fully developed state represents a collection of lymphocytes, it would appear quite unlikely that it should possess functions different from other collections of lymphocytes.

On the other hand if the essential elements in the organ are epithelial, they may well, like the epithelial elements of the thyroid, or of other glands with an internal secretion, be concerned in the elaboration of substances which exert an important influence on growth and nutrition.

While there are various views as to the nature of the cellular elements the view of Maximow (3) and Hammar (4) has most supporters at the present time. They believe that the thymus is an epithelial organ containing lymphocytes. They also believe that the thymus reticulum represents the remnant of the original epithelial nature of the gland, and that this reticulum persists, even after involution has occurred. They think further that the organ is of a twofold nature and may function both as an epithelial and a lymphoid structure. This conception is of fundamental importance. If we attempt to show that the thymus is concerned in the production of an internal secretory substance, we must somehow admit that it contains an epithelial structure.

From the foregoing statements, it is evident that opinion is divided as to whether the thymus is an

Copyright, 1926, by A. R. Elliott Publishing Company.

organ of internal secretion, or whether it has a function similar to that possessed by other hematopoietic organs, such as the spleen and lymph glands.

Sajous's (5) opinion is that the thymus is not the source of an internal secretion. He considers that its function is to supply through the agency of the lymphocytes, the excess of nucleins, which the body requires during the period of accelerated growth. The osseous, nervous, and genital systems need an extra supply during infancy, childhood or even adolescence.

The nucleins are needed in the rapid multiplication of the cellular structures.

He also believes that the thymus gland supplies nucleins in abundance, that it takes part in the oxidation and autoprotective processes of the body, and that it has some important relations to phosphorus metabolism.

Physiologists have pointed out that the nuclein substances characteristic of the nuclear framework of the true glands are much more abundant in the thymus than in the lymph glands.

Hoskins (6) reports a definite relationship between the involution of the thymus and a decrease in the percentage of lymphocytes in the blood.

Friedlander (7) thinks that the thymus functions as a lymphoid organ in infancy and childhood because of the presence of the large number of leucocytes, especially lymphocytes in the blood, during the earlier years of life, and that they must be important in the growth of the organism. He believes that their presence in increased number is bound up with the question of immunity and resistance to infection which occurs in all animals.

ORGAN OF INTERNAL SECRETION

The earlier experiments of Basch (8) who attempted to show the internal secretory function of the gland and its intimate relation to thyroid action, as well as his theory that thymus extirpation caused disturbances in the intelligence of the experimental animal, have not been corroborated by more recent investigation. Basch thought that after extirpation of the thymus an increase in the electric excitability occurred similar to that occurring after extirpation of the parathyroid.

The observations of Basch were confirmed by Klose (9), Vogt, and Matti (10). These latter observers thought the abnormally obese animals produced by extirpation of the thymus had developed rickets. Later experiments were conducted by Svehla (11) who injected thymus extracts, implanted thymus glands and fed thymus substance. He believed that intravenous injection of dried thymus substance in solution caused a fall in blood pressure and had a specific effect on cardiac rate and respiration. Sometimes sudden death occurred.

These experiments were not corroborated by subsequent investigations. If Svehla's work had proved the specific action of this extract, he would have had evidence of the internal secretory function of the thymus gland. But the significance of an endocrine gland depends entirely upon the proof of a specific secretion and its characteristic effects.

This proof is still lacking in the case of the thymus. But it should not be considered that the thymus is a superfluous organ. The very fact of its presence during birth and young life and its persistence in rudimentary form, suggest at least that it has a place in animal function.

Whether it is necessary to life has not been proved. Congenital absence of the thymus has been described in the new born and its absence has been accidentally discovered due to death from intercurrent diseases. How often it may remain undiscovered is altogether in the realm of speculation.

According to Park and McClure (12) the symptoms and pathological changes following thymus extirpation are almost without exception due to the changes which occur in laboratory animals as the result of confinement, improper food, unhygienic conditions, bacterial and parasitic infections.

These experimenters conclude that the thymus is not essential to life in the dog. They find that extirpation of the thymus produces no detectable alteration in the hair, teeth, contour of the body, muscular development, strength or activity of the experimental animal. Extirpation of the thymus probably does not influence growth or development nor produce alteration in the organs of internal secretion.

In contradistinction to the experiments of Park and McClure, one still finds it stated in standard textbooks of physiology that there seems to be a relation between the thymus and the sex glands.

Calzolari (13), Henderson (14), Paton (15), and others find that castration would seem to delay the involution of the thymus, and might even cause thymic hypertrophy. On the other hand, after thymectomy there is often a hypertrophy of the glands. According to Hoskins (16), a definite relationship has, however, not as yet been proved. The function of the gland may differ in various animals.

Gudernatsch (17) showed that in feeding thymus gland substance to tadpoles their growth was increased after feeding the gland substance twenty days; they were twice as large as at the beginning of the experiment. He thought that the increase in size depended more on swelling or imbibition than on cellular growth.

Abel (18) says that in man the thymus occupies a doubtful position as an organ of internal secretion, though in some of the lower animals such as birds he believes that the thymus undoubtedly produces internal secretion.

The investigations are divided as to the relationship between the thymus and the organs of internal secretion. It is obvious that the solution rests upon the fundamental fact of whether the thymus produces an internal secretion. In Finkelstein's (19) recent textbook he states that he is inclined to the opinion that removal or absence of the thymus causes changes or hypertrophy of the organs of internal secretion such as thyroid, adrenal, testes, ovaries, and pancreas. This opinion, as has already been indicated has not been concurred in, nor does it seem conclusively proved, by the experiments of numerous investigators.

The relationship of the thyroid gland to the thymus has also been investigated. Herdinger (20) found seven cases of enlarged thyroid in twelve cases of so-called thymic death in the newborn.

There are many reports which show a combination of exophthalmic goitre and thymic hyperplasia. McKenzie (21) noted in thirty-six postmortems on

patients who died of exophthalmic goitre the most constant feature next to an enlarged thyroid was an enlarged or persistent thymus. Confronted by all this confusing evidence, as well as by the uncertainty of the morphological nature of the gland, we are in agreement with modern investigators that the endocrine function of the thymus in man is doubtful or at least not proved.

PATHOLOGY

The thymus is readily affected and the parenchyma reduced by acute infections and chronic diseases. Involution occurs not only as the result of disease but also after nutritional disturbances, particularly starvation. The röntgen ray causes rapid reduction in the size of the gland. It is also atrophied in certain animals during the period of hibernation.

Pregnancy in the human being as well as in certain animals causes the thymus to diminish in size. It is conceded by a majority of investigators that involution may be produced by inanition. In this condition, the diminution in the number of Hassall's corpuscles is the characteristic feature. If the underfeeding continues for a long time and constitutes an actual condition of starvation, the child's thymus may undergo a marked atrophy. The cortex diminishes in size, until a mere remnant remains, the principal part of which is composed of compressed reticulum cells containing lipoid material. Under these circumstances the medulla atrophies as well. The gland may come to weigh only one or two gms. whereas the normal gland weighs about fifteen gms. It is reported by some that an atrophied thymus in an undernourished or hungering child may become normal in size and structure, if the child's nutritional state returns to normal. Conversely, it has been thought that the gland might be increased in size by feeding, though there seems to be no evidence in favor of this view.

Involution of the thymus is also produced by the röntgen ray. In two or three hours after irradiation a wholesale disintegration of the lymphocytes takes place while the reticular cells resist to a greater extent, and tend to remain intact for a longer time. The disintegrated lymphocytes and their nuclei are taken up by the reticular cells in the manner of phagocytes and there they seem to be digested and dissolved. The reticulum persists and as has been suggested the thymus devoid of lymphatic cells, with persistent reticulum, constitutes an epithelial organ.

Circulatory disturbances may occur in the thymus as a part of a general circulatory disease. In newborn infants hyperemic disturbances have been described in hyperplastic thymus glands. Apoplexy or hemorrhages into the thymus have been described in various infections, measles, pertussis, pneumococcus infections and phosphorus poisoning. Acute inflammatory changes in the thymus have been observed in diphtheria, erysipelas, variola, and measles.

THYMUS ABSCESSES

Primary abscess formation may occur as the result of an acute inflammatory thymitis.

SYPHILIS

Hemorrhage may occur into the parenchyma of the gland as the result of congenital syphilis. Most frequently, however, the luetic lesion in this location consists of an interstitial inflammation. Less often gummata are found. Associated with the gumma are frequently observed Dubois abscesses. It has been shown that they are due to fetal arrest of development on a syphilitic basis and spirochetes have been found in the wall of the cyst, which naturally clarifies the specific nature of the disease. The socalled Dubois abscesses are usually multiple, the cysts contain a turbid fluid resembling pus. They vary in size from peas to hazel nuts; occasionally some of the smaller cysts coalesce to form a large cavity in the gland.

TUBERCULOSIS

Primary tuberculosis of the thymus is extremely rare. Occasionally the gland becomes infected from a mediastinal lymph gland. Under these circumstances miliary tubercles or a large caseous mass may be observed.

Sclerosing atrophy of the thymus may occur as a result of cachectic conditions or it may be observed after syphilis, tuberculosis and severe types of intestinal infections. It has been supposed by some authors that the atrophy of the thymus was the cause of the general atrophic condition of the infant. We believe, however, that the diminution in size of the gland is secondary to the general inanition.

NEOPLASMS

The benign tumors of the thymus such as are observed in adults are rare in children. Malignant tumors are more frequent in the latter—sarcoma, lymphadenoma and lymphoma. The literature contains a report of twenty-two cases of sarcoma in young life. Tumors of epithelial origin are rare in childhood. On the other hand, leucemia may produce myeloid tumors of the thymus. Other conditions such as pseudoleucemic tumors and chloroma may occur. Hassall's corpuscles are usually observed in tumors of the thymus gland.

HYPERPLASIA

The most frequent and most interesting change that occurs in the thymus is diffuse hyperplasia. Whether a hyperplasia actually exists can only be demonstrated with accuracy at postmortem. Even under normal conditions the weight and size of the organ are subject to great variations and for this reason it is difficult even to differentiate a normal from a pathological gland. The size and weight of the thymus is in a certain way proportional to the general nutrition. If the infant loses decidedly in weight the gland diminishes in size, though this is not a constant condition.

The anatomical diagnosis of hyperplasia is established more frequently now than formerly. In well nourished children the gland may be considered hyperplastic if it weighs more than twenty grams in the first year and twenty-five grams in the second year. Hammar (22) gives the following table of normal weights of the thymus at various ages:

Years	*Grams*
Newborn	13.26
6-10	26.1
11-15	37.52
21-25	24.73
56-65	16.08
66-75	6.

On the other hand, it must be recognized that there are great individual differences. In atrophic children,

the thymus may show a normal weight, but this should not be considered as an expression of a pathological condition. The normal as well as the hyperplastic thymus may be demonstrated by physical examination. If one practises light percussion one may map out the organ as an irregular triangular dullness, the apex of which reaches to the second rib and the lateral dullness may extend to each sternal line or even beyond.

Dullness which extends one cm. beyond the limits stated may be considered abnormal. Calcified mediastinal glands may give similar findings. The x ray may aid in recognizing thymus enlargement. The interpretation of the shadow must be made with great care. A hypertrophy should be accepted only when the middle shadow lies over the heart and extends beyond the sternovertebral shadow. As a rule the mass appears larger on the left than on the right. A similar shadow is caused by the veins of the mediastinum, or by marked venous distention. These conditions occur readily in cases of dyspnea and are frequently confused with thymus hypertrophy. The shadow produced by the veins is broader on the right than on the left; it is also increased in the vertical direction. The shadow also changes with respiration and in deep inspiration it may disappear. There are instances that show that the gland may weigh thirty-five, forty or even fifty grams. Even today the teachings concerning the hyperplasia of the thymus gland are not clear.

The significance of thymus hyperplasia is not cleared up and the view that laryngismus stridulus is a form of thymic asthma due to the pressure of the swollen gland on nerves is obsolete. It has been shown that a large gland may be unassociated with laryngismus and on the other hand laryngismus may occur without enlargement of the gland. Congenital laryngeal stridor is frequently explained on grounds other than thymic enlargement. The enlarged organ is in many instances suspected of having a causal relation to respiratory disturbances, to heart affections and to sudden death.

HYPERPLASIA AND RESPIRATORY DISTURBANCES

It is possible that thymic hyperplasia may be the cause of dyspnea. Cases have been described in which a persistent dyspnea occurred either shortly after birth or after several months, or even in the second year of life.

In many of these cases symptoms of suffocation occur, and increased thymic dullness may be demonstrated. Occasionally a portion of the gland may be felt, tumorlike, above the upper thoracic opening, i.e., the sternal notch, particularly during the period of expiration. In these cases tracheotomy gives no relief. Unobstructed breathing may only be established by introducing a tube as far as the bifurcation of the trachea. The obstructive symptoms may also be made to disappear if the gland is detached from the trachea and bronchi and sewed to the sternum, or if the extrathoracic part is excised.

In some instances the dyspnea may be caused to disappear if the patient is turned on his abdomen. In all probability the cause of the socalled asthma thymicum is stenosis of the trachea due to pressure or it is due to a wedge shaped thickened portion of the gland which presses on the bifurcation. Possibly under some circumstances there may be pressure on the nerves. This is analogous to the experience with goitre which may produce suffocation without tracheal stenosis.

It should be observed, however, that the conditions noted are rare in comparison with the frequency of thymus hyperplasia and if they occur at all they must depend on definite changes in size and shape of the gland. In considering all these facts, Finkelstein (23) says he has never seen a case which belongs to the class described above, and all of these cases which he at first called thymic asthma, and which were described by the röntgenologist as thymic hyperplasia, were always found to be due to another cause if carefully examined. In addition to this he says that many surgeons of the largest experience hold the same view, though other observers from other regions have in a short period of time described whole series of cases.

Is it possible that geographical variations occur as in the case of goitre? Finkelstein (24) further remarks that the diagnosis is too frequently made without due consideration. The diagnosis is based on the expiratory congenital stridor, dyspnea either continuous or remittent, suffocative attacks, dullness over the sternum and a typical sternal shadow in the x ray picture. The dullness and the x ray shadow may both be due to distended veins in this region. In some instances the diagnosis may be confused with cardiac asthma.

THYMIC CONSTITUTION

The most important and constant symptom which has led to the diagnosis of status thymolymphaticus has been the thymus death. Experience from various quarters has shown that in both children and adults the most insignificant procedures and traumata have caused death. Some have died while bathing, others after insignificant wounds or after a slight whipping or emotional excitement. A case is reported where a child was turned on his abdomen because of dyspnea. He suddenly became blue, dyspneic and in a few minutes death had taken place. Autopsy showed no adequate cause of death. There was no aspiration of stomach contents. The thymus weighed twenty-four grams, was obviously enlarged. The parathyroids and adenoids, microscopically at least, showed no changes. On gross examination it was found that the mesenteric glands and lymphatic structure of the intestine were enlarged. The heart was dilated and relaxed. Medical men are particularly interested in the deaths which ensue from minor manipulations and operations and the administration of an anesthetic. Death had been reported after a salvarsan injection, and the autopsy showed status thymicolymphaticus.

Arnold Paultauf (25) was the first to describe status thymicolymphaticus. He assumed that the condition was a lymphatic chlorotic diathesis in which the most important anatomical characteristics were general hyperplasia of the lymphatic tissue and thymus, a small heart and narrow vessels. Such individuals are likely to die suddenly, death being due to a cardiac failure.

Lubarsch (26), in considering the whole subject is rather skeptical as to the prevailing theories concerning the relationship between sudden death and thymic and lymphatic hyperplasia. He believes that it will be a fruitful source of knowledge to investi-

gate the relationship between the adrenal and thymus, and particularly to study the thymus in all serious diseases of the adrenals. He also says that it cannot be denied that there may be such a condition as status lymphaticus although the anatomical conditions ascribed to this affection may be found in all acute and chronic affections such as measles, scarlet fever, whooping cough, tuberculosis, and syphilis; also in nutritional disturbances as well as pharyngeal and tonsillar infections.

Not infrequently, he says, where a diagnosis of thymic death has been made the lethal result has been found to be due to acquired secondary conditions and not to a constitutional anomaly. He reports the case of a child where the diagnosis of thymic death was made by a young pathological assistant, but careful examination showed that death occurred from streptococcus sepsis.

The generally accepted conception of status thymicolymphaticus, consists of a general hyperplasia of the lymphatic system and an enlargement of the thymus, though enlargement of this organ may be absent. The medullary substance of the adrenal body is frequently hyperplastic. The heart is commonly dilated and hypertrophied. Young infants and children who present this condition of status lymphaticus have a swollen, pale appearance. They are often fat, have low resistance to disease and often die suddenly during acute infections.

In death from status lymphaticus, the end comes suddenly and unexpectedly with symptoms of heart failure. The patient falls, respiratory difficulty occurs, characterized by cyanosis and dyspnea, the superficial veins are distended, a few twitchings occur, sphincters relax and the patient becomes livid.

During the course of hyperacute toxemia, rather suddenly or unexpectedly, restlessness and anxiety are observed as well as dyspnea. Diarrhea associated with rapid loss of weight and unconsciousness occur. Twitchings are frequent. Very significant and constant is the agonal rise in temperature which may reach 105°, 106° or 107°. Occasionally sudden death occurs associated with laryngismus stridulus and sudden syncope. It has been thought in some instances the lethal issue was due to spasmophilia and not to lymphatic constitution.

Other forms of hypersensitiveness must be considered. Possibly some cases, where the patient in the course of a few hours is attacked by high fever and coma, in a few hours terminating in death, depend not only on the infection but the low resistance of the child. A similar significance may be attached to the chronic nutritional disturbances and to the debility which results from undernutrition. Infections and alimentary influences may lead suddenly to toxic states and death.

In another small group the adrenal body may suffer from infection. An acute hemorrhage may occur into this organ and sudden death results. The tendency to sudden death in both varieties of cases may depend in some degree on the action of the adrenal bodies. If the secretion is diminished the effect of the blood pressure raising influence is removed as well as the maintenance of vascular tonus, possibly also damaging the heart and the tonus of the circulation.

TREATMENT

If we assume the correctness of the theory that symptoms may be due to an enlarged thymus, we must adopt some method of treatment which will reduce the size of the organ. Friedlander (27), in 1904, was the first to treat enlarged thymus glands with the x ray. He has shown clinically and experimentally that it is possible to produce involution of the thymus by this method of treatment. Friedlander and Lange (28) exposed the thymus region of animals to the x ray. They demonstrated that the spleens of the experimental animals showed reduction in number, size and clearness of the malphigian corpuscles. They treated 250 cases with two deaths. In mild cases a single treatment over the anterior surface of the chest is sufficient to bring about improvement. Usually the intervals between treatments has been one week unless the urgency of symptoms has suggested more frequent applications.

Friedlander (29) says no ill effects have followed the use of x ray treatment in competent hands, though a case is recorded by M. J. Konikow (30) where tetany occurred following x ray exposure of the thymus in a baby five weeks old. It must be assumed in this case that the rays caused atrophy of the parathyroid glands.

RADIUM

Several observers have used radium as a substitute for the x ray and report favorable results. The radium is filtered through silver and the tube is placed over the anterior aspect of the chest, directly over the thymus gland. It is stated that only one treatment is required and that there is no danger in one treatment.

DRUGS

No results have been obtained nor are any to be expected from the use of drugs.

SURGICAL TREATMENT

The first operation was done by Rehn (31) in 1896. He detached the thymus from the underlying organs and sewed it to the sternum. The results of this operation were not favorable. Later Vean and Oliver (32) contrived the operation of thymectomy. Parker (33) in his monograph, 1913, showed that the mortality from this operation was thirty-three per cent. The operative treatment has been almost entirely superseded by the x ray treatment.

SUMMARY

1. It is doubtful whether the thymus is the source of an internal secretion in human beings. It is probable that it supplies the excess of nucleins which the body requires during the period of accelerated growth.

2. It should not be considered that the thymus is a superfluous organ.

3. On the other hand, extirpation of the gland in the dog does not influence growth or development, nor does it seem to produce alteration in other organs of internal secretion.

4. A certain number of observers still maintain that there seems to be a relation between the thymus and the sex glands.

5. Reports seem to indicate that exophthalmic goitre may produce at times thymic hyperplasia.

6. The thymus participates in a variety of dis-

eases. It atrophies during starvation; general circulatory disturbances affect the gland. It may also be the site of abscess, acute inflammation, syphilis, neoplasms, sclerosing atrophy.

7. The gland reaches its greatest weight from the eleventh to the fifteenth year. From this time on it gradually atrophies though remnants in most cases continue throughout life.

8. Large thymus may cause dyspnea in young children, though the obstructed breathing is frequently due to other causes.

9. Status lymphaticus is a condition in which the most important anatomical characteristics are hyperplasia of the lymphatic tissues and thymus, a small heart and narrow vessels. Such individuals are subject to sudden death.

10. The treatment of enlarged thymus consists of the use of x ray or radium. Surgical treatment is obsolete.

Chronic Hereditary and Familial Hemolytic Jaundice

With Splenomegaly and Hepatomegaly: Observations on Five Cases Under Study

WALTON FOREST DUTTON, M.D.
Amarillo, Texas

The chief purpose of this report is to place on record the results which have followed the treatment of chronic hereditary and familial hemolytic jaundice with splenomegaly and hepatomegaly by nonsurgical procedures differing in essential principles from those clinical methods of management in present general or special practice.

In order that a better concept of this comparatively rare condition may be presented, a résumé is a fitting introduction. Chronic hereditary and familial hemolytic jaundice with splenomegaly and hepatomegaly is closely related to the disease described by Murchison, in 1885, by Minkowski (1) in 1900, and by Chauffard (2) in 1907, as congenital or familiar hemolytic jaundice. The characteristic features common to both conditions are the marked increase in the number of reticulated red blood cells, and the great fragility of the red cells when exposed to hemolytic agents. They differ in the very decided functional activity of the liver and its relation to the reticuloendothelial system.

The course of these conditions is, in many ways, much the same, simulating pernicious anemia; it is one of crisis followed by periods of remission, but is not necessarily fatal. In some cases, as one now under study, the patient lives to the sixth decade. As a rule, a crisis follows fatigue, excitement, indiscretion in diet, stimuli to the vegetative nervous system, or acute infection. In the splenomegalic type, the patient vomits much bile, the spleen enlarges and becomes tender, and there may be a great increase in the degree of anemia present, with an absence of the concomitants of ordinary obstructive jaundice, such as light stools, choluria, pruritus and slight icterus. Chronic hereditary and familial hemolytic jaundice with splenomegaly and hepatomegaly shows the marked variation of obstructive jaundice with slight subicteric discoloration of skin and scleræ.

HEREDITY

The cases under study represent three generations in which the condition is traced back to and including two previous generations. Sex does not appear to be a factor in the transmission of disease. (Fig. 1.)

JAUNDICE

Jaundice, in these cases, has been present from birth. Crises bring about signs of obstruction of the bile passages; the stools are free of bile pigment, while the urine contains urobilin. These observations do not agree with the findings in the cases reported by Barker (3), Lewis (4), Giffen (5), and Krumbhaar (6).

I am inclined to think that their cases were not of the true type or that the cases now under study are atypical. This would seem improbable, on account of the meagre information available. Bilirubinemia is present, but not marked as in pernicious anemia.

In explanation of the pathogenesis of jaundice of this type, it is obvious that jaundice is due most frequently to impairment of the excreting function of the liver. That is to say, the condition is usually traceable to inflammatory or degenerative changes of the liver cells. Mechanical or other obstruction to the outflow of bile causes the bile to back up in the liver cells. This action damages the cells by inflammatory or degenerative process and facilitates the accumulation of preformed bile in the liver cells. The excretory function may be inhibited without impairment of other functions.

The spleen is enlarged, firm, and usually movable and seldom tender except during a crisis. It may extend five to eight finger breadths below the costal margin. The liver frequently extends from one to three finger breadths below the costal margin in the mammillary line.

The anemia, urine, and stools, factors of relative etiology, pathology and diagnosis have been freely discussed in the preliminary report (7). A summary of the cases under study, as presented at that time, noted that they differed from the usual forms of hemolytic jaundice. They differed in the very decided functional activity of the liver and its relation to the reticuloendothelial system.

During the periods of crisis, the concomitants of ordinary obstructive jaundice, such as clay colored stools, choluria, mild pruritus, and slight icterus are present. The blood picture is markedly characteristic, but at times exaggerated. This makes the diagnosis comparatively easy. An intimate study of these cases appears to implicate the extra hepatic bile passages and the reticuloendothelial system. In the production of crises, the neuromuscular reflex apparatus of the bile passages plays an important rôle. A total spasm of the region of the sphincter of Oddi with contractions of the gallbladder, which force bile back to the columns of the liver cells, produces a toxic irritative process of defense reaction in the hemopoietic apparatus.

REPORT OF CASES

Case I.—Mrs. C. B., a widow, aged fifty-six, height sixty-four and three quarter inches, weight 104¾ pounds, temperature 98°F., came under my service, November 11, 1924, complaining of attacks of gallbladder trouble and of indigestion. She stated that she had had a large spleen and liver since childhood; the grandfather had had liver trouble and enlarged spleen and died at the age of seventy of pneumonia; the grandmother died at ninety of old age; the father died at thirty-two of liver trouble; the mother was living and well at seventy-six; one paternal uncle and one paternal aunt died of liver trouble; one uncle died of abscess of the spleen; three children died in infancy; two daughters were living, one in apparent good health at thirty, who had had a cholecystectomy at twenty-nine; one in fair health at twenty-nine, who had had a splenectomy at twenty-six. Investigation revealed that these spleens were not enlarged from tuberculosis, syphilis or malaria.

The patient's habits had been good; she was of a nervous temperament. She had had the commoner diseases of childhood; socalled bilious fever at twelve; influenza in 1890, and frequent attacks since that time. The patient injured the lower end of the spine by a fall when sixteen; the forearm was broken two and five years before I saw her.

Examination of the respiratory apparatus was negative. The pulse was 78; there was occasional tachycardia; the radial arteries were palpable, and were not calcified; the heart and the aorta were normal. There was no dyspnea and no edema. The blood pressure was 100 systolic and 70 diastolic.

Blood examination revealed: red blood corpuscles, 4,120,000; hemoglobin, 60 per cent.; white blood corpuscles, 8,100; differential count: polymorphonuclear neutrophils, 48 per cent.; polymorphonuclear eosinophils, 1 per cent.; polymorphonuclear basophils, 1 per cent.; small mononuclears, 38 per cent.; large mononuclears and transitionals, 10 per cent.; a few normo-

Fig. 1.—Occurrence of chronic hereditary and familial hemolytic jaundice with splenomegaly and hepatomegaly in five generations: All patients lived in the same community within the radius of half a mile. The cases reported in detail were: Case 1, IV, 1; Case 2, VI, 3; Case 3, VI, 1; Case 4, V, 4; Case 5, V, 5. L. and W. means "living and well."

blasts. Anisocytosis and poikilocytosis were marked. The blood platelets numbered 900,000. A few megalokaryocytes were seen (iron hematoxylin stain). The blood, stained with brilliant cresyl blue, showed reticulation of the red cells to thirty per cent. Test of red cells to salt solution showed that hemolysis began at 0.6 per cent. and was complete at 0.4 per cent. The color index was 0.8. The spleen was somewhat tender and movable, and extended four finger breadths below the costal margin. The Wassermann reaction was negative.

Attacks of indigestion and gallbladder trouble dated back to the age of twelve, but the patient had not associated the condition with enlargement of the spleen. Gaseous eructations and abdominal pain were relieved only by a hypodermic injection of morphine. Paroxysms came on at irregular intervals, varying from six months to two years. Pain occurred frequently after eating. There was slight constipation. Physical examination revealed the liver extending two finger breadths below the costal margin in the right mammillary line. The patient complained of tenderness on palpation of the right upper quadrant. The gallbladder was markedly enlarged, and stones were easily recognized. The stomach contents contained no free hydrochloric acid; the total acidity was thirty-eight per cent.; there was no occult blood; there were no Oppler-Boas bacilli. The duodenal

contents consisted of viscid fluid, neutral to litmus, and turbid; the bile was thicker and darker than normal; there were fragments of bile thrombi. The feces contained bile and urobilin, except during a crisis.

Examination of the urogenital apparatus showed hydronephrosis of the right kidney. The urine was normal except for indican and urobilin; there were a few casts and white corpuscles. The phenolsulphonephthalein output was forty per cent. in two hours. The pelvic examination was negative.

No mental anomalies were detected. The patient slept fairly well. There were occasional cramps in the limbs. Bilateral deafness had existed since 1890. There was slight pruritus after attacks of pain in the gallbladder. The scleræ and skin had a slight subicteric tint.

During the past year the patient had two mild attacks in which the crises were of short duration. Prophylactic measures were observed. Gastrointestinal sedatives were administered as required. Iron and arsenic were given by mouth. General condition was fair. Blood examination February 20, 1926: red blood corpuscles, 3,200,000; hemoglobin percentage 56 Newcomer; color index, 0.8; white blood corpuscles, 12,000. Differential count: polymorphonuclears, 53; lymphocytes, 35; transitionals, 2; eosinophils, 5; basophils, 5. Abnormal: normoblasts, 2; megalokaryocytes, 2; Turk's irritation form, 1; erythrocytes, abnormally small; marked polychromatophilia; some poikilocytosis. Reticulated cells 32 per cent. Fragility began at 0.49 per cent., and was complete 0.40 (control 0.44-0.34). Icterus index, 6.

Case II.—R. R. J., a boy, aged six, height forty-seven inches, weight forty-nine pounds, temperature 98.6° F., came under my service, November 17, 1924, complaining of headache, and pain in the left side (on exertion), and socalled biliousness. These conditions had existed since birth. He was the grandson of Patient 1. The father was living and well at twenty-seven; the mother was living and in fair health at twenty-nine; one brother was living and in good health at four; there were no sisters. In 1923, he had a slight attack of influenza.

The chest was normal. The right middle turbinate was enlarged. The nasal septum was deviated. The tonsils and adenoids were hypertrophied. The pulse was 80; the heart, normal. There was no dyspnea or edema. The blood examination showed: red blood corpuscles, 3,650,000; hemoglobin, 50 per cent.; white blood corpuscles, 7,800; differential count: polymorphonuclear neutrophils, 46 per cent.; polymorphonuclear eosinophils, 2 per cent.; polymorphonuclear basophils, 1.5 per cent.; small mononuclears, 39 per cent.; large mononuclears and transitionals, 8 per cent. There was marked anisocytosis and poikilocytosis. The blood platelets numbered 1,100,000. diminished resistance of red cells to salt solution began at 0.7 and was complete at 0.5. The color index was 1. Reticulated cells were 34 per cent. The lymph glands were normal. The spleen was hard, was movable, and extended five finger breadths below the costal margin. The Wassermann reaction was negative. The Pirquet test was negative.

The appetite was good. There were no eructations. The bowels were regular. During the attacks, the stools were clay colored and frothy. Palpation of the liver edge showed that it extended two finger breadths below the costal margin in the right mammillary line. The patient complained of slight tenderness over this area. Otherwise the examination of the abdomen was negative.

The patient voided a large quantity of dark, orange brown urine the first thing in the morning and several times during the day, but not at night. The urine was normal except for urobilin. The skin and the scleræ had a slight subicteric tint during exacerbations.

This patient had had three slight attacks during the past twelve months. The phenomena presented were much the same as noted before. The treatment was the same as given in Case I. August 14, 1925, tonsils and adenoids were removed. Blood examination, February 27, 1926, showed: red blood corpuscles, 3,560,000; hemoglobin percentage, 45 Newcomer; white blood corpuscles, 8,400; color index, 0.6. Differential count: polymorphonuclears, 23; lymphocytes, 75; basophils, 2. Abnormal: normoblasts, 1; myelocytes, 2; marked poikilocytosis; some achromia; marked anocytosis. Reticulated cells 12 per cent. Fragility beginning at 0.48 per cent. and complete at 0.36 per cent. (Control: 0.44-0.34.) Icterus index, 8.5.

Case III.—W. S. B., a boy, aged eight years, came under my service November 26, 1924, complaining of pains in the stomach and frequent headaches. The father was living and well at thirty-nine. The mother was living and in fair health at thirty. One brother was living at nine months, under treatment for rickets. There were no sisters. The patient had scarlet fever in 1921; whooping cough in 1923, and measles in 1924. A tonsillectomy was performed in August, 1924.

The respiratory and circulatory apparatus were normal. The blood examination revealed: red blood corpuscles, 3,100,000; hemoglobin, 60 per cent.; white blood corpuscles, 7,900; differential count: polymorphonuclear neutrophils, 48 per cent.; polymorphonuclear eosinophils, 1.5 per cent.; polymorphonuclear basophils, 1 per cent.; small mononuclears, 40 per cent.; large mononuclears and transitionals, 10 per cent.; a few normoblasts. There was considerable anisocytosis and poikilocytosis. The blood platelets numbered 980,000. The fragility test of the red corpuscles showed that hemolysis began at 0.58 per cent. and was complete at 0.36 per cent. The color index was 1.1. Reticulated cells numbered 20 per cent. The lymph glands were normal. The spleen was hard, was movable, and extended two finger breadths below the costal margin. The Wassermann and tuberculin tests were negative.

The patient had a good appetite. There were no gaseous eructations. Pain in the stomach occurred only at the time of a crisis, at various intervals extended from three months to eighteen months. The bowels were regular. Physical examination showed the liver extending one finger breadth below the costal margin in the right mammillary line; otherwise it was negative. The stools during exacerbations were clay colored. The urine was normal except for the dark, orange brown color and the presence of urobilin. The skin showed an earthy tint; the scleræ showed a slight subicteric tint, which was more marked at the time of the crises.

The usual prophylactic measures were carried out in this case. Improvement was satisfactory. The patient suffered one mild attack. Iron, arsenic and nuclein were administered intravenously.

Blood examination, February 20, 1926, revealed the following: red blood corpuscles, 4,880,000; hemoglobin percentage, 79 Newcomer; white blood corpuscles, 11,000; differential count: polymorphonuclears, 67; lymphocytes, 30; mononuclears, 1; eosinophils, 1; basophils, 1; erythrocytes very small; platelets slightly increased; marked crenation; color index, 0.8; reticulated cells, 17 per cent.; fragility began at 0.48 and was complete at 0.36; icterus index, 6.5.

Case IV.—Mrs. J. B., aged thirty, came under my service, September 15, 1924, complaining of weakness and a general rundown condition. She was the daughter of the patient in Case I and the mother of the patient in Case III. She had the more usual diseases of childhood and had had socalled bilious attacks since childhood. There was nothing unusual in the personal history except that when three months pregnant with the last child it was found necessary to remove the gallbladder during an attack. The gallbladder contained many stellate stones, which rapidly disintegrated after several weeks. Following childbirth she was confined to bed with septic fever. Since that time she had felt "generally all in," but after removal of the gallbladder had not had any bilious attacks.

The patient was fairly well nourished. Her lips were pale, and her skin presented a peculiar subicteric tint. The temperature was normal. The pulse rate was slightly accelerated, being 84 to the minute. The rate of respiration was 20 a minute. The thorax was normal. The edge of the spleen was on a level with the costal margin. The spleen seemed fairly hard, but movable. There was no marked tenderness. The liver, on palpation and percussion, was normal in size. The patient complained of a little tenderness in the right upper quadrant. Examination of the abdomen was otherwise negative. Pelvic examination revealed a lacerated perineum and laceration of the cervix uteri. Blood examination revealed: red blood corpuscles, 4,200,000; hemoglobin, 80 per cent.; white blood corpuscles, 7,850; differential count: polymorphonuclear neutrophils, 80 per cent.; polymorphonuclear eosinophils, 8 per cent.; small mononuclears, 18 per cent.; large mononuclears and transitionals, 6 per cent. The platelets numbered 400,000. The fragility test was normal: 0.45 and 0.3. The reticulated cells were 3 per cent. The Wassermann reaction of the blood serum was negative. The digestive apparatus showed nothing unusual. The urine was normal except for a trace of indican.

An examination of this patient November 23, 1925, showed a decided increase in weight. The general health during the past year was unusually good. Blood examination: red blood corpuscles, 4,520,000; hemoglobin percentage, 85 Newcomer; white blood corpuscles, 11,000. Differential count: polymorphonuclears, 63; lymphocytes, 30; mononuclears, 2; eosinophils, 4; basophils, 1.

February 26, 1926, this patient was stricken with an attack of influenza which precipitated the only bilious attack she had experienced since the first examination on September 15, 1924.

Examination on March 6, 1926, showed spleen on level with costal margin; slight subicteric tint. Blood examination: red blood corpuscles, 3,780,000; hemoglobin percentage, 67 Newcomer; white blood corpuscles, 12,600; polymorphonuclears, 63; lymphocytes, 31; mononuclears, 2; eosinophils, 3; basophils, 1; no crenation or anicytosis; color index, 0.9; reticulated cells, 3 per cent.; fragility: 0.52-0.40. Icterus index, 7.

Case V.—Mrs. L. R. J., daughter of the patient in Case I and mother of the patient in Case II, seen October 10, 1924, had been under the service of Dr. H. Z. Giffen of the Mayo Clinic for observation and treatment. Dr. Giffen wrote that the patient came under his observation, August 19, 1921. She had been well up to the age of eight years. At that time she became quite anemic, but not especially jaundiced. Later occasional attacks of intermittent jaundice developed until the time of operation. During the eight months preceding her visit to the Mayo Clinic she had had more trouble than formerly.

The spleen was considerably enlarged. The red cell count was 2,900,000, and the differential count showed nothing of especial significance. A reticulated cell count was high, nine per cent., and the fragility of the red cells was definitely increased. At that time a history of the mother's condition was obtained. She stated that the mother had an enlarged spleen and had been jaundiced for about twenty-five years. The mother's father was said to have died of some sort of liver trouble. One child of the patient was said to be anemic and to have recurrent socalled bilious attacks. Splenectomy was done, September 27, 1921. The spleen weighed about 1,000 gm.; gallstones were not present. The common duct was normal; the appendix contained fecal concretions and was removed. Exploration was otherwise negative.

A reexamination was made of the patient on May 5, 1925. This revealed, in addition to the condition outlined above, incipient pulmonary tuberculosis involving the upper left lung. There was dyspnea on exertion. Weight, 105 pounds. Blood pressure: 100 systolic, 70 diastolic. Blood examination: red blood corpuscles, 3,800,000; hemoglobin percentage, 70; white blood corpuscles, 8,200. Differential count: polymorphonuclears, 55; eosinophils, 1; basophils, 1; small mononuclears, 30; large mononuclears, and transitionals, 5; few normoblasts; some poikilocytosis; blood platelets, 600,000. Fragility test: Hemolysis began at 0.5 per cent. and was complete at 0.38 per cent. Codliver oil was prescribed in addition to the general supportive diet. Iron cacodylate, sodium cacodylate and nuclein were administered, twice weekly, intravenously. Blood examination March 6, 1926: red blood corpuscles, 4,460,000; hemoglobin percentage, 66 Newcomer; white blood corpuscles, 13,200. Color index, 0.7. Differential count; polymorphonuclears, 40; lymphocytes, 60; very slight poikilocytosis; myelocytes, 1. Reticuled cells, 4 per cent. Fragility began at 0.48 and was complete at 0.40. Weight, 135 pounds. General condition excellent. Icterus index 9.

TREATMENT

The treatment of this disease should not be confused with that of splenomegalic jaundice, hemolytic icterus, or congenital hemolytic jaundice. Chauffard (9) reports a case of congenital hemolytic jaundice in

a woman, aged forty, in which splenectomy resulted in the disappearance of the jaundice within a few days, and in an apparently complete recovery. Examination of the blood two years later showed marked improvement, but hemolysis was still evident. No granular erythrocytes were found (before the intervention they ranged from twelve to fifteen per cent.). It appears, according to Chauffard, that the bone marrow, affected by the altered spleen, protects itself by producing granular erythrocytes. The toxic condition of the marrow and the fragility of the blood corpuscles long persist, but do not provoke any noticeable reaction. Splenectomy checks the destruction of the blood corpuscles (the spleen process); while the improvement of their fragility occurs later (the marrow process). Evidently, in this condition, the jaundice and the hemolysis do not depend on each other and may be dissociated by removing the spleen.

These conditions are similar to the disease under discussion, but, strictly speaking, pathologically different. For this reason the surgical and nonsurgical methods of attack are essentially diverse. As noted in this and the previous report, the case of splenectomy was followed by marked improvement; in the case of cholecystectomy, the patient apparently completely recovered.

The severer the affection, the shorter the interval between crises. This is governed by the degree of inflammation, contraction of the ducts and the involvement of the sphincter of Oddi. In the milder cases the duodenal tube introduced after the method of Meltzer-Lyon is frequently a prompt palliative measure; the severe cases may necessitate removal of the gallbladder or spleen. Nonsurgical procedure in three cases has proved eminently satisfactory.

The predisposing causes of the crisis should be taken under consideration, proper diet, regular exercise, fresh air and sunlight, freedom from excitement and sudden changes of temperature, and the prevention of infections, are essential prophylactic measures. Iron, arsenic, and nuclein plus heliotherapy have proved useful therapeutic agents. Asher (10) has submitted experimental evidence to support such therapy. It has been my experience, however, that research problems of this type are best approached in a condition of pathological process rather than in a physiologically normal state. Iron, arsenic, and nuclein were administered by mouth and hypodermically with only fair results. The best results have been secured by the intravenous method. Improvement has been marked during the course of treatment. The spleen and liver have been reduced in size, the blood picture has improved, the crises ameliorated and the intervals extended in the three cases without operation. In the cases where operation was performed the patients responded unusually well.

It is to be inferred from the studies made to date that the close cooperation of the surgeon and internist will prove the solution of the problem presented by chronic hereditary and familial hemolytic jaundice with splenomegaly and hepatomegaly.

Metal Poisoning by the Administration of Colloidals*

N. ALPERT, M.D.
Baltimore, Md.

Prompted by the recent developments in the use of colloidal metals in the treatment of malignant diseases, many commercial pharmaceutical houses in the United States and abroad have begun to manufacture selenium, copper, gold, manganese, and lead in colloidal form and to distribute literature to practitioners advocating their use in nonoperable and postoperative malignancies. A few cases, benefited by skilful hands, are described to the general practitioner in a way to convince him of the immense therapeutic value of these metals. The physician, impressed, thereupon uses the colloidal metals in his cases of malignancy, without realizing and without being properly informed of their toxic and dangerous effects.

The earliest investigators of the properties of these colloidals were well aware of their toxic nature. Wassermann and Keysser, in 1911, concluded that selenium, to be used as a therapeutic agent, would have to be combined with some other substance that would carry it into the malignant cell itself, so that it could unfold its lethal action locally without injuring the normal tissues. Working with a selenium-eosin compound which had been found very effective in treating animal tumors, Wassermann learned that when the method was tried on human beings, the dose necessary to destroy the tumor also killed the patient. Kausch, working with colloidal silver, obtained good results with human tumors, but also found severe toxic symptoms with death resulting in one patient, so that his method has been abandoned. More recently, W. Blair Bell, of Liverpool, has emphasized that great care must be exercised in the selection of proper patients for treatment with colloidal lead, because of its toxic effects.

*From the Homewood Hospital, Baltimore.

In order to use the metals, certain careful observations must be made as to the determination of the malignancy: the part or organ involved, with or without metastasis; the toxicity of the patient as a result of the malignant condition; the blood chemistry; the renal function; the hemoglobin and blood picture in general. The tolerant test must be established in terms of c. c. per body kilogram. Attention should be paid to the radioactivity of the blood, or, better still, after each injection there should be a checking up of the blood by the nitric acid and iodine test, and the changes in the blood picture noted. The patient's urine should be examined carefully; once a day is not too often.

The two following cases, referred to me, will amply serve as a warning to physicians contemplating for the first time the administration of colloidal metals in their treatment of malignant diseases. They will illustrate what great care must be taken to ascertain the proper dose at the proper time.

CASE I.—The patient, a female, thirty-five years of age, weight before malignant condition 125 pounds, present weight 100 pounds, with nonoperable carcinoma of the cervix, was receiving from her family physician five c. c. colloidal selenium intramuscularly every other day. Although the malignancy improved greatly, after six injections the following symptoms developed: flushed face, dilated pupils, nausea and vomiting, severe headaches, pain in abdomen, cramps, suppression of urine, extreme prostration, sudden fall in blood pressure. Though the body was cold to the touch, the patient complained of great heat and air hunger. The pulse was 40 a minute, irregular, and weak; heart sounds were weak and irregular in rhythm, with hemic murmurs in pulmonary and aortic areas; respiration 30 a minute. The liver was enlarged and the edges were palpable; spleen was palpable; gasus-fremitus in lower intestines.

A catheterized specimen of the urine revealed the following: reaction highly acid; specific gravity 1040; albumin 4 plus; sugar one plus; acetone and diacetic acid present; indican 4 plus; hyalin and epithelial cells numerous; granular cast and pus cells also numerous. Blood count: hemoglobin 45 per cent.; red blood corpuscles 2,000,000; white blood corpuscles 10,000; differential count, neutrophiles 50 per cent.; large and small lymphocytes 18 per cent.; normoblasts and megaloblasts present. Coagulation time seven minutes. Blood chemistry: urea nitrogen 75.0 mg., uric acid 10.05 mg., amino acid nitrogen 20.0 mg. Due to lack of blood, no other blood chemistry could be performed.

Patient was removed to the hospital and the following treatments begun: sodium thiosulphate, one gram intravenously every four hours; 1000 c. c. physiological salt solution with 10 mns. adrenalin by hypodermoclysis; heat applied externally; one half ounce whiskey given, followed by the free use of liquids.

The patient's condition improved, in that toxicity from the colloidals was reduced. When such toxicity disappeared, a tolerant test was established and treatments were resumed with selenium. The blood was checked up and the radioactivity noted. Present blood picture: hemoglobin 68 per cent.; red blood corpuscles 3,200,000; while blood corpuscles 14,000; differential: neutrophiles 85 per cent.; normoblasts occasional. Blood chemistry: urea nitrogen 25.0 mg., uric acid 6.5 mg., amino acid nitrogen 10.0 mg. Since the malignant condition improved, the patient's weight was increased from 100 to 112 pounds. The patient is still under treatment.

However, it is important to note that the great improvement of the patient's condition came only after a normal dose was established by the tolerant test, and a definite rule laid down as to when and how the colloidal metal should be administered.

CASE II.—The patient was a male, forty years of age; former weight 135 pounds, present weight 115 pounds, with carcinoma of the rectum without metastasis. Received from his family physician colloidal copper injected intramuscularly, five c. c. every other day. The following symptoms made their appearance after eight injections: slight burning in the esophagus, pain in abdomen, nausea and vomiting, cramps followed by violent diarrhea and bloody stools, excessive thirst, suppression of urine, prostration, fall in blood pressure. Stools contained rolled flakes of mucus and epithelial débris. Liver was enlarged with palpable edges; a palpable spleen. Severe pain prevented further examination of abdominal wall. The patient breathed laboriously and was air hungry; pulse 50 a minute, irregular and weak; heart sounds irregular and weak; no murmurs.

A catheterized specimen of urine gave the following findings: reaction highly acid; specific gravity 1040; albumin 4 plus; sugar 1 plus; acetone and diacetic acid present; indican 4 plus; hyalin and epithelial cells numerous; granular cast and pus cells also numerous. Blood count: hemoglobin 60 per cent.; red blood corpuscles 3,400,000; white blood corpuscles 14,000; differential count: neutrophiles 65 per cent.; normoblasts and megaloblasts present; coagulation time eight minutes. Blood chemistry: urea nitrogen 80.0 mg., uric acid 15.5 mg., amino acid nitrogen 25.0 mg., cholesterol 290.0 mg., nonprotein nitrogen 75.0 mg.

Patient was removed to the hospital and the following treatments begun: sodium thiosulphate, one gram intravenously every four hours; 1000 c. c. physiological salt solution with ten mns. adrenalin by hypodermoclysis; heat applied externally; caffeine sodiobenzoate seven and a half grains hypodermically every five hours.

Here also the patient's toxic condition improved and the following blood changes found: hemoglobin 75 per cent.; red blood corpuscles 4,200,000; white blood corpuscles 10,000; neutrophiles 80 per cent.; normoblasts occasional. Blood chemistry: urea nitrogen 25.0 mg., uric acid 8.0 mg., amino acid nitrogen 10.0 mg., cholesterol 180.0 mg., nonprotein nitrogen 38.0 mg.

After a normal dose was ascertained by the tolerant test and the colloidal metal used correctly, the patient's malignant condition improved more. The patient is still under treatment; he is gaining weight, the discharge from the rectum is decreasing, and he is free from pain.

CONCLUSIONS

The colloidal metals, although of great value in malignant diseases, must be used with great care and with a constant check on the blood and the kidneys. Where such care is not exercised, we find that to the

misery of a patient suffering from a malignancy has been added the effects of a toxic agent which, instead of accomplishing its original purpose of prolonging the life of the patient, succeeds only in shortening it drastically in more misery.

Let us note again that these conclusions are not what is termed a sudden discovery. Many of those who worked with metals in malignant diseases, such as Wassermann and Keysser, and recently Bell, have emphasized the same danger of using the colloidal metals without a careful regard to the consequences.

Bothriocephalus Latus*

THEODORE ROSENTHAL, M.D.

New York

Cases of infestation by tapeworms are not at all uncommon in this country. Instances of Bothriocephalus infestation are, however, more unusual and merit discussion not only for their comparative rarity, but because of the toxic phenomena which frequently accompany them, and which may simulate other conditions.

Thus, Savitz (1) describes a case in which gastric symptoms and secondary anemia were prominent features, and malignancy of the gastrointestinal tract was feared, and only after several negative röntgenographic examinations was parasitic disease suspected. Again Grünmandel (2) reports an instance of a pernicious type of anemia in a child with hemolysis following a blood transfusion. Repeated small transfusions from a different donor were employed, and then vermifuges given with prompt recovery.

Up to 1916 Singer (3) was able to find only thirty cases of Bothriocephalus infestation reported in this country; Haden (4) collected twelve more instances in 1923, and since that time Riley (5) and Anderson (6) have published additional reports.

Most of the cases described have occurred in immigrants, but Calvin (7) and Wallace and Grant (8) report several instances of native born infection. These cases occurred in the Great Lakes region, in children of immigrants who partook of raw fish. According to Stiles it is probable that immigrants have infected the fish in these regions and that there exist in this country numerous foci of infection.

A critical analysis of the cases previously reported fails to disclose any unusual signs and symptoms, other than those classically described. Not all the patients presented an anemia; Haden concludes that in about ten per cent. of those harboring the parasite at some time anemia develops.

Eosinophilia is not a constant finding. Calvin, in reviewing all the cases of tapeworm infection in the Cook County Hospital from 1911 to 1921, stated that in seventeen of thirty-three cases in which blood counts had been recorded, eosinophilia was present.

Various theories have been entertained as to the cause of the anemia. It was thought that the lipoids of the worm might be a hemolytic agent. Attempts to reproduce an anemia with extracts of normal worm failed. Faust and Tallquist (9) observed that worms recovered from patients with anemia show as a rule great loss of substance, with little change in lipoid content. They advanced the theory that through the death of the parasite in the intestinal canal of the host, hemolytic substances were formed and absorbed, bringing about the characteristic action on the blood and bonemarrow.

Brumpt (10) agrees with the authors quoted above but noted that in Switzerland anemia is rare, and common in the Baltic region and Russia, although the disease is endemic in both areas. No explanation is advanced for this apparent discrepancy.

Oleoresin of aspidium was the drug employed by the majority of the authors; this was given after several days of fluid diet and following saline cathartics. One author (Savitz) obtained a successful result with thymol.

Jacobaeus (11) found that the proportion of cases in which the head of the tapeworm was evacuated was considerably increated by using veronal and phenacetin in conjunction with male fern medication. Six grains each of veronal and phenacetin were given on three evenings in succession, before administration of the vermifuge. This also seemed to reduce the tendency to vomit. Schneider (12) obtained excellent results by using small amounts of oleoresin of aspidium introduced directly into the duodenum by means of the duodenal tube.

In none of the reported cases was there any evidence of inquiry into the blood findings and other laboratory data which might lead to some further knowledge of the cause and course of the blood changes which occur in this type of infestation.

It was for this reason, in addition to the rarity of these cases, that this report has been prepared.

Case.—Mrs. L. S., aged fifty-four, a housewife. The patient's family history was irrelevant. She was born in Austria and had lived in the United States for twelve years. Thirteen years ago she first noticed a portion of a worm in her stools. She sought medical advice and medication was given without success. One year ago and two weeks prior to admission she again passed segments of worms. The patient felt well and suffered no loss of appetite. Occasionally she had abdominal pains and a feeling of hunger, but this soon passed off.

*From the Lebanon Hospital, New York City, service of Dr. William Weinberger.

She had had asthma for the past five years, typhus and influenza twenty years ago. The respiratory organs were negative, also the cardiac and gastrointestinal. Her appetite was always good, bowels regular, and no jaundice at any time. The genitourinary organs were negative. She had been married twenty-six years, had had three children, who are alive and well, and one miscarriage. The menopause occurred six years ago.

The patient had always been fond of fish, and had eaten it all her life. She said that about twenty-three years ago while preparing some fish she found a tapeworm in one of them. She had never eaten raw fish, it had always been cooked.

Physical examination revealed a short, stout, white female, aged fifty-four, not looking ill. Her heart was slightly enlarged to left, and there was a slight systolic murmur at the apex. The lungs showed fairly good resonance; expiration prolonged; no râles. Abdomen showed obesity, no masses or viscera palpable. No edema in the extremities. The patient's weight was 145 pounds. Blood pressure, 132/80.

Blood counts on two occasions were as follows:

Hemoglobin (Dare)	52 per cent.	60 per cent.
Red blood cells	3,500,000	4,000,000
White blood cells	5,400	8,400
Polymorph. leucocytes	74 per cent.	72 per cent.
Lymphocytes	22 per cent.	20 per cent.
Mononuclears	2 per cent.	6 per cent.
Eosinophiles	2 per cent.	2 per cent.
Platelets	200,000	

The urine was straw colored, clear, specific gravity 1,022, no albumin, sugar or casts; a trace of urobilin was present. Phenolsulphonephthalein test: first hour, fifty per cent.; second hour, fifteen per cent.; total two hours, sixty-five per cent.

Stools were semisolid, brown. Repeated examinations showed moderate numbers of typical Bothriocephalus latus ova. No blood, either gross or occult, could be demonstrated. Pancreatic ferments were present, and a slight trace of hydrobilirubin. Total fat 0.91 per cent. The blood Wassermann was negative.

BLOOD CHEMISTRY

Nonprotein nitrogen	32 mgms. per 100 cc.
Urea nitrogen	15 " " " "
Uric acid	2.2 " " " "
Sugar	141 " " " "
Carbon dioxide combining power of plasma	44 vols. per cent.
Cholesterol	192 mgms. per 100 cc.
Icteric index	4.1
Bilirubin dilution	1-35.

Stomach contents: Fractional gastric extraction revealed a normal curve of acidity, ranging from 22 free and 34 total acidity to a maximum of 24 free and 88 total acidity. Microscopic examination negative.

Duodenal contents: Obtained by Lyons drainage, revealed some débris. No ova were found. A culture of the contents showed the presence of Staphylococcus aureus (probably a contamination).

Red blood cell fragility was found to be normal. Hemolysis began at 0.44 per cent. and was complete at 0.36 per cent. Surface tension of blood serum 141.6 grams (normal). Semidentation rate of erythrocytes—32 minutes to mark iii; (normal in two hours).

After observing the patient for a few days she was prepared for the treatment by having a liquid diet for two days. On the day before receiving the anthelmintic, she was given licorice powder in the morning and an ounce of magnesium sulphate at night. The following morning after drinking a cup of black coffee the patient took eight capsules, each containing fifteen minims of oleoresin of aspidium. These were taken within a half hour. Thirty minutes later she was given five grains of calomel and after an equal length of time she again took one ounce of magnesium sulphate. An enema was given soon after, and the patient expelled a worm eighteen feet long.

On gross examination it was seen to be a typical specimen of the Bothriocephalus latus with flat segments perhaps two centimetres broad at its widest point and diminishing in the neck region to a breadth of no more than one millimetre. Close search failed to reveal the head and subsequent enemas given also proved fruitless, but the presence of so much of the neck region made us confident that the head had also been expelled.

After the worm had been obtained, conjectures were made as to the possibility of visualizing it *in vivo* inasmuch as we had been employing sodium-tetraiodophenolphthalein in cholecystography. Accordingly different portions of the worm were immersed in a ten per cent. solution of the dye for thirty minutes, six hours, and twenty-four hours respectively, and then washed free of all dye and exposed to the x ray. Fine shadows were obtained but these results did not warrant proceeding any further along these lines.

SUMMARY

A case of Bothriocephalus infestation is presented, with a report of the laboratory findings and a review of the literature. Nothing abnormal was encountered in the investigation. Absence of anemia, eosinophilia, and marked symptoms in this particular instance evidently indicate that the worm had not died in the host, with the resulting absorption of toxic products. The appearance of the worm also tended to support this view.

The icteric index, performed as described by Bernheim (13), was well below the normal maximal figure. The sedimentation rate of the erythrocytes of the patient, described, among others, by Alexander (14) and Zwecker and Goodell (15), and which as a rule indicates the presence of acute inflammation, was found to be normal.

Blood morphology and red cell fragility were also normal. The surface tension of the blood serum, determined through the courtesy of Dr. H. L. Frosch, was found to be normal, although as yet there is no literature available on this physical property of the blood.

In this instance of tapeworm infection, then, no indication of faulty function of the hematopoietic system is seen. This patient, however, presented practically no clinical signs other than the mere presence of the worm in the stool.

It is hoped that when well marked cases present themselves, these findings will serve as a point of departure for future investigations, which will help to shed more light on the blood changes occurring in this disease.

141 WEST 120TH STREET.

The Chemical Aspects of Life and Disease*

ELLICE McDONALD, M.D.
Philadelphia

(*Concluded from page* 461)

This was called the smooth muscle reaction (the involuntary muscle is also called smooth muscle) because it was the reaction of the involuntary muscle to the varying influence of the two sides of the vegetative nervous system.

An interesting fact was then disclosed: when the vagus was preponderant, the condition of the blood was more acid (increased hydrogen ion concentration) and when the sympathetic division was preponderant, the blood was more alkaline (decreased hydrogen ion concentration, increased p.H.). This meant that nerve action was associated with and influenced by chemical conditions of the body. This fact was so surprising that it was investigated at length, and finally it was found that the degree of acidity or alkalinity of the blood (hydrogen ion concentration) could be more or less exactly determined by the condition of the involuntary muscle, particularly in the intestine, as shown by x rays under certain specific conditions of the test. In order that there be no mistake due to scientific enthusiasm or uncontrolled deduction, an investigator, skilled in mathematical analysis, was asked to make a test of the correctness of our deductions. It was found that, by means of x ray pictures, with all details concealed, except the image of the intestinal muscle, it was possible to predict the hydrogen ion concentration of the blood (degree of acidity or alkalinity) with a small margin of error. So a correlation table was plotted (which showed an extremely small factor of error) not to tell us what we believed before, but to remove the factor of human fallibility and proneness to error and to give us an idea of how far right we were and how far wrong.

The vegetative nervous system and the degree of acidity or alkalinity of the blood then worked together or could be reciprocally correlated (mutually affecting and affected). It was also found, generally speaking, that, when the blood was made more acid, the vagus division became preponderant and, when the blood was made more alkaline, the sympathetic division became preponderant. Confirmation was found in the work of Daly and Clark, and Drury and Cowles, who found that when the liquid around the heart was acid, the heart beat slower (vagus action) and when the liquid was alkaline, the heart beat faster (sympathetic action).

The action of the four important elements showed that there was the same antagonism between sodium and potassium upon the one hand and calcium and magnesium upon the other, as was found by Murkerjee in his test tube experiments upon negatively charged suspensoids. The salts of the first two increased the action of the sympathetic side and the salts of the last two increased vagus action. Calcium and magnesium salts do not make the blood alkaline, but make it acid, as has been proved by the work of Blackfan, Gamble Hamilton, ourselves and others. The reason of this is not at present clear; but, in biological experiments with one celled organisms, such as the star fish egg, it has been consistently proved that the salts of sodium and potassium increase the permeability of the membrane (or cell wall) and increase the conductivity, while the calcium and magnesium salts decrease the permeability of the outer boundary and decrease conductivity.

The reason of this may be in the fact that sodium and potassium have one electron in the outer ring and calcium and magnesium have two outer electrons. This difference of action may have to do with the same processes as produce the Compton-Einstein light effect, for when a particle of light collides with a free electron (as in sodium and potassium) the light waves are changed from a higher frequency to a lower—from blue towards red—by impact with the free electron. In other words, with the impinging of the "light quant" (or light unit) on a free electron, it necessarily transfers some of its energy to it, but the "light quant" recoils from the impact with a lesser energy and to a lower frequency. But, when there is no free electron, the mass of the atom permits the momentum equation to be satisfied without forbidding the complete transfer of the energy as it does when there is only one free electron. Then again, sodium and potassium are acted upon by the whole spectrum of light and are higher in the order of conductivity and calcium and magnesium are acted upon by the ultraviolet part of the spectrum. As all energy comes from the sun, this action of the ultraviolet light in mobilizing calcium may be most important.

In the study of man and his processes, it is difficult to get the healthy ones to stay put long enough to study them properly. In the army, during the late war, we had control of them, but we were too busy about another job. However, when he is sick and in a hospital, it is possible to keep him long enough to study him more or less continuously to his benefit and not to his hurt. So most of our observations upon the processes of human life have been in the deviations from normal which are called disease and, from this it is possible not only to gain knowledge about the deviations, but also of the manner of return to normal and of normality itself. The result of these researches may be shown in the following scheme which has to do with the relation of the force (energy), the apparatus (protoplasm) and the controlling influence (the vagus sympathetic balance of the vegetative nervous system), and only secondarily with the deviations from balance of normality, called disease. (See table on page 539.)

From this table it may be seen that an even balance of the vegetative nervous system is necessary to the proper maintenance of the equilibrium of the chemical processes of the body which we call health. "He who has health has hope, and he who has hope has everything." Disease deviates the balance to one or other side and deviation of balance to one or other

*Address before the American Chemical Society, April 15, 1926.

side predisposes to certain diseases. By this is not meant that this is the cause of disease (it probably is of many nonbacterial diseases), but that it produces a receptive condition for disease and probably for the bacterial infections. Pneumonia, for example, is prevalent in winter when the ultraviolet content of light is low, the green vegetables have lost their chlorophyll (a vagus stimulant) and the blood content is low in anions (the acid part of salts, such as iodine), so that the incidence of pneumonia may, indeed, be due to a sympathetic preponderance and a receptive condition of the lung cells for the pneumococcus which is almost always in our throats.

Disease is usually a terminal result from predisease conditions with transient or recoverable changes (transitory cell changes) to culminate in a condition of permanent symptoms (permanent cell changes) without recovery, or in disease which is an irreversible reaction (or the balance is more or less perma-

nently upset until the man gets well or dies). A man does not die because he gets disease: he gets a fatal disease because he is dying. All diseases are more or less terminal (like age, which is essentially a disease) and differ only in degree in that respect. The symptoms of disease are but the expression of a foregoing condition and the result of altered cell function for a varying period of time before sufficient accumulated deviation results in disease.

In consideration of diseases it is interesting to know that most bacteria which produce infection are negatively charged, while the antibodies which neutralize infection are positively charged. Antibodies are apparently catalysts of the second order and it may be that they are of the nature of protective colloids. The quality of charge is of importance as it has been found in the four types of pneumococcus that virulence decreased with decreasing charge.

Apparently reduction of charge is one method of recovery from infection. In the typhoid bacillus, for example, the negative charge is approximately —15 mv. If this is reduced the cohesive forces overcome the repulsive force of the charge and the bacilli fall together and agglutinate, so that the progress of the disease is dependent upon the reduction of the negative charge through the body forces.

Positively charged substances such as ferric hydroxide, manganous chloride and sodium recinoleate increase the effect of antitoxins, provided these are in excess, apparently by increasing their positive charge. The unsatisfied bond of sodium recinoleate has a strange and powerful action. Of course, charge is only a product of chemical changes. All the processes of infection and immunity can be explained upon the basis of colloid chemistry. There is great hope that the control of infection may come through the production of chemical antibodies and these will in all probability be positively charged compounds of the univalent elements.

In certain acid vagus types of disease, benefit is derived from treatment by the injections of positive colloids of the type of ferric hydroxide colloid as in asthma. Again, in the alkaline sympathetic types of disease, the negatively charged substances are of use. The ferric hydroxide colloid seems to act as a protective colloid so that the cell acquires the isoelectric point of the protective colloid and then the positively charged antibody is effective.

As three of the fundamental principles of man's life have been considered, it remains to consider the influence of psychic processes. In the study of emotion we have found that this also divides itself into two phases. Emotion of the type of despair or fear is characterized by activity of the smooth muscle of a vagus or active type, while anger or fighting fear is marked by sympathetic action shown in the immobility of the smooth muscle of the stomach. This last is the type of emotion which Cannon produced in cats when he showed there was an increase of adrenalin, a sympathetic stimulant in the blood.

Emotion thus has a chemical influence by its production and the emotion of either type is more easily felt according to the nearness of the chemical balance of the system. Fear of the despairing character is more readily felt by the acid vagus type, while anger or fighting fear is more readily felt by the alkaline sympathetic, high blood pressure type.

Emotions, then, must be considered as falling into two classes; the vagus effect producing and the sympathetic effect producing and in these effects they have a decided influence upon body processes and body chemical metabolism (and all metabolism is chemical). Such familiar phrases as "the shock upset my digestion" come to mind. One of our most beautiful x ray pictures is of a temperamental young woman about to faint, and shows the stomach contracted into a knot to such a degree as to be almost impossible of belief, so marked is the vagus effect upon the contraction of the muscle.

This has also been correlated in modes of thought. There is in psychology a very definite type of thinking marked by different levels of consciousness. This is called the hysterical thinking of the type of Janet, —the *somnambule* or hypnotizable subject. Our collaborator, Dr. Elton Mayo, has found that patients of this hysteria type are always upon the alkaline

sympathetic side. This led to the study of the opposed type of obsessional thinking person with the overregulated life, full of fears and worries and he was found to be of the acid, vagus type. These two types are quite definite examples of the opposed deviation from normal thinking, and there are all possible gradations. This discovery has promise of far reaching results, because, for the first time, modes of thought, or manner of mental processes have been correlated qualitatively with chemical processes and hope of future discovery is bright in this direction.

The two branches of nervous force, voluntary and involuntary, have thus been correlated more or less with chemical processes:—the vegetative nervous system with p.H. and smooth muscle effects and obsessional and hysterical thinking with p.H. and the vegetative nervous system. The vagus, acid type has exaggeration of obsessional thinking more readily than the obsessional sympathetic alkaline type, and more readily feels anger, worry and irritation. While the hysterical alkaline, sympathetic type more readily feels anger and thinking upon different levels of consciousness. So modes of thought and tendency to certain emotions can be correlated with chemical changes in the human body.

In the production of these changes in the human body, the important substance is the protein of the colloid cell. Fat and carbohydrate are more or less dead tissue and do not enter into the control of the chemical balance as shown, for example, in immunological reactions. Protein, however, establishes the differentiation between the different species and different individuals as proteins of different species show readily recognizable immunological differences as in the precipitin test and these differences in protein are apparently dependent upon chemical composition.

Proteins are complexes of amino acids of which seventeen go into the formation of protein and Abderhalden has calculated that, if all are in protein, there are 2420 different compounds without calculating the enormously greater number which might be made by varying the proportions in a different protein. An interesting suggestion has recently been made by Troensegaard that proteins are not made up of amino acids, but that the amino acids are decomposition products and that protein is built largely of pyrrole, pyrrolidine and pyridine rings condensed into systems of 2, 3 or more and containing O as OH. This is the more interesting as specific differences seem to depend upon the aromatic radicals and protein can be altered by introducing such radicals as iodin, NO_2 and N=N into the protein molecule, where they are known to enter specifically into the benzene ring of the aromatic amino acids. These proteins, when so changed, as with iodine, produce immunological reactions which are specific for the changed protein, but are also specific for all iodized proteins. Iodized protein precipitin is not specific for proteins changed by nitrogen dioxide or other radicals. Furthermore, if radicals are introduced which do not possess the benzene ring, species specificity is not affected, although the resulting proteins exhibit specificity towards themselves. This seems to indicate that the aromatic radicals may be of importance in determining biological reactions. The important factor seems to be the relative location of the aromatic nucleus of the acid and diazo group. The specific behavior of protein is, therefore, determined by the chemical structure of relatively small portions of the large protein molecule. Peck also believes that electric charges on the amphoteric colloidal protein (antigen) and antibody and also their surface configuration and surface forces all influence the reactions of protein.

The specific behavior of protein is thus determined by chemical structure, but the mechanism of colloid forces must also be considered as to adsorption, change of sign and spatial arrangement.

The dependence of biological specificity upon proteins raises the question as to how proteins became specific. There cannot have been any changes in the character of protein for a vast period of time. The earliest known forms of life existing show that their chemical composition is essentially the same as that of their living descendants. The oldest proteins available for such purposes are those of the mummy and the mammoth. Human proteins of five thousand years ago have no evolutionary alteration from human proteins of the present day. The blood of the Siberian mammoth of twenty-five thousand years ago gives immunological reactions which indicate its relation to the modern elephant.

The selection of the seventeen amino acids must have been made at an immensely remote period for the earliest records of life do not show us organisms which have any noteworthy difference in chemical composition. Nor do we find any amino acids which do not exist in plants. Bacteria and plants can synthesize protein from extremely simple inorganic salts and the chemical structure of unicellular organism is equally complex with the cells of man. Some questions for chemists are "why do the evolved proteins possess so great a variety of amino acids, and why is it that none of the other related amino acids, other than the seventeen used, occur? Why is it that proteins may contain amino acids with two, three, five and six carbon atoms, but never with four carbon atoms?"

The human protein is, therefore, the important deciding factor, and in protein itself the important part seems to be the aromatic radical. There may be then said that there is a protein constant for each particular individual and the processes of life written into a formula, incomplete, because our knowledge of life is incomplete, but capable of revision and addition with increasing knowledge.

$$K = \frac{BHCO_3 \times OH \times Sr \times Es}{H_2CO_3 \times H \times So \times Ev}$$

Let K = The protein constant of protoplasm (or "gift")
$BHCO_3$ = Fixed alkali of univalent cations
H_2CO_3 = Fixed acid of bivalent and trivalent cations and all anions
OH = Free hydroxyl ions
H = Free hydrogen ions
Sr = The reduction part of the oxidation reduction poise in the sense of Mansfield Clark
So = The oxidation part of the oxidation reduction poise
Es = Sympathetic effect producing emotions
Ev = Vagus effect producing emotions.

This formula embodies the sum of environmental influences of life, affecting the original protoplasm or "gift" of our first single cell from which we de-

veloped after its fertilization. So that included in the factors following the constant, K, are all the influences which modify it through life and so alter it that, when it reproduces itself, the quality of protein is once more renewed into a new K.

Life is an equilibrium as is shown in the constant temperature of the human body, which is a product of chemical forces, as are many other manifestations of the human balance. In the human tribe, then, is a different quality of balance due to different protein constant and different environmental influence. The darkeyed, largepupiled Mediterranean races of the south of France, Italy and Spain are inclined to sympathetic preponderance. One example of this is the number of subjects among them capable of being hypnotized. Hypnotic suggestion, according to our researches, bears a very definite relation to sympathetic preponderance. So that these people react differently to emotion to the fair haired, blue eyed Nordics of Germany with their vagus preponderance. They differ not only in their protein constant, but also in their environmental influences (for example, the greater meat consumption of the German). How then can they be expected to understand each other when they react differently to emotion and in mental processes?

The vagus sympathetic balance implies balance or proportionate association of salts, particularly sodium, potassium, calcium and magnesium with proper hydrogen ion concentration and the production of proper bioelectric variation in the cell and liquid phase (the blood and tissue juices). Of course, life is not rigid, but mobile so that this balance fluctuates with the daily occurrences of life within moderate limits, for example, in the alkaline tide after food which temporarily neutralizes the acid of the stomach. Still it is probable that most of us have a predilection or tendency toward the one side or the other, toward the vagus preponderant or the sympathetic preponderant or we would not grow old, and this has a great deal to do with determining character and temperament.

Feeling and emotion, which, after all, determine our actions and course in life much more than intellectual reason, must play a great part in our relations with our fellows. If the vagus preponderant is more prone to worry, fear and the anxieties, it will be hard for the sympathetic preponderant whose reactions to these same stimuli are different, to understand him, except by an effort of conscious willed analysis, but not naturally and automatically.

The basis of man's life is then dependent upon his special structure, the quality of his material and the atomic forces which activate them. Also must be considered the mechanism of the control of the relations of these factors in the unconscious nerve control of his protoplasmic processes. The striking fact in the study of man's processes is the elaborate and extreme symmetry and arrangement, balance and counterbalance, as there is in all nature. No thinking man can ponder on the processes and arrangement of life and living things without feeling that these are too precise, too arranged, too planned to be without direction and that when scientists endeavor to explain these processes and their evolution, they do not detract from faith, but make the meaning of the Maker more increasingly manifest.

Twentieth and Chestnut Streets.

Congenital Genu Recurvatum*

With Report of a Case

SAMUEL W. BOORSTEIN, M.D., F.A.C.S.
New York

While rare congenital skeletal deformities are interesting as is a rare case of any disease, these cases have perhaps additional importance for the general practitioner. In college and in the general textbooks all these deformities are little more than barely mentioned. Their etiology and treatment are certainly neglected. The student invariably remembers that they are incurable. During his busy practice he seldom reads medical periodicals devoted to one subject exclusively and thus misses the latest treatment for these rare cases. Even when an article on the subject is published in the general medical journal he is quite apt to omit it from his reading. The result is that the physician remains with the impression that they are incurable. When he is so unfortunate as to find that a child delivered by him has a rare congenital deformity, especially a skeletal, he sympathizes with the parents and in as soft a tone as possible informs them that the condition is incurable. The parents console themselves as best as they can but when the child is a little older the mother is usually advised by neighbors of the proper institution to which the child is to be taken. There the mother is frequently told that the child can be improved or even cured. The parents of course at once put the blame for the delay to their family physician. Quite naturally such an occurrence does not add to the good repute of the physician. It is therefore advisable for the general practitioner to see these congenital deformities once in a while and thus keep in touch with their latest treatment. They might perhaps establish a rule to have the cases seen by a consultant within a few days after birth and to let him decide whether the condition is curable or not. Such a procedure will save the family physician hours of anxiety, and the patient months of disability.

The consideration of the above prompted me to report this rare case especially when I have the good fortune to be able to demonstrate how it has been put on the road towards a perfect cure.

The case was on the service of Dr. H. J. Epstein, the Visiting Obstetrician of Bronx Hospital, who showed me the child when only three days old.

*From the obstetric service of Bronx Hospital. Presented before the Clinical Society of the Bronx Hospital Dispensary on December 14, 1925.

Genu recurvatum is an anterior displacement of the tibia. The knee is bent somewhat backward, or in other words the leg is hyperextended on the thigh. This deformity is so rare as to receive but little mention in the standard texts. Jones and Lovett in their latest book do not speak of this deformity at all. Albee (1) just mentions the occurrence. Whitman (4) and Steindler (3) do give more space to that

FIG. 1.—September 19, 1925, when child was six days old (before treatments were instituted). Note the marked recurvatum of right knee. (This photograph was unfortunately taken by an amateur photographer and thus the shading is not proper but it brings out the deformity clear enough.)

deformity. The condition is often spoken of as anterior dislocation but this term should be limited to the more extreme cases.

It is considered to be due to abnormal and fixed position in the uterus. It is therefore mechanical in nature. "In some cases it may be due to aplasia of the quadriceps with secondary bone changes" Bazert (2). The patella is usually rudimentary.

CASE.—M. S. Female; first child; born of healthy parents. Labor, vertex, no forceps.

Child was seen by me on September 16, 1925, when only three days old. Examination showed a distinct recurved or hyperextended right knee. No marked contraction of the quadriceps tendon as the leg could be brought down to a straight angle but could not be flexed. There was a marked groove above the patella. One could feel the patella (Fig. 1).

The x ray showed no abnormality but of course one could not make a reliable interpretation of a radiogram at such an age.

A small Thomas Jones splint with the knee in straight position and traction straps was applied. In two weeks the splint was flexed slightly at the knee. The angle of flexion was gradually increased so that at the age of six weeks the leg was flexed at an acute angle. Massage was then instituted three times a week removing the brace at each treatment. When child was two months old the brace was taken off for one hour twice a day. The time was gradually increased. Now at the age of three months it is off about four hours daily. I hope to be able to dispense entirely with the brace in another month.

The physical examination of the patient at present shows no defect in the knee. Child moves it as freely as the other and does not hyperextend it. Kicks freely. Has no groove above the patella. Good power of the quadriceps (Fig. 2 and 3). Naturally the child will have to be watched when it commences to walk in order to see that it places the feet normally. It is my opinion that it will.

It may also interest you to know how easy it was to take care of the child. The mother (who fortunately happened to be intelligent) was shown the function of the brace and also where pressure is likely to occur (at the ring) and instructed her how to remove the felt padding and recover the ring. After the first two weeks the mother knew how to take off the brace, bathe the child while the knee was guarded, and then to reapply the brace. Thus the difficulty of keeping the child clean was easily overcome.

CONCLUSIONS

1. Congenital genu recurvatum is amenable to treatment.
2. The treatment should be commenced immediately after birth.
3. A small Thomas Jones splint can be used to keep the limb in the proper position.

FIG. 2.—December 21, 1925. When child was three and one half months old. Note the good condition of the knee..

FIG. 3.—December 21, 1925. See the ability to flex the knee freely.

4. Massage and exercises can be used easily with this brace.

I wish to thank Dr. H. J. Epstein, the Visiting Obstetrician of Bronx Hospital, for his kindness in referring the case so early and permitting me to make these observations.

Tissue Fibrinogen by Mouth in the Treatment of Acute Hemorrhage in Hemophilia*

LLOYD B. DICKEY, M.D.
San Francisco, California

While a physician is not often called upon to arrest the hemorrhages of a hemophiliac, a very discouraging problem may be offered when such a patient presents himself. The many and various types of therapeutic measures adopted in these cases is evidence of this fact. Mills (1) has repeatedly advocated the use of tissue fibrinogen to control the bleeding in hemophilia as well as in other types of hemorrhage, and lays claim to attaining marked success with this substance, although he has submitted no case reports. In two cases on our service, in one of which most of the conventional methods had failed to check the hemorrhage, we used tissue fibrinogen by mouth, with good results.

CASE REPORTS

Case I.—A. M., an infant one year of age, of Scotch ancestry, was circumcised on May 29, 1925. Almost immediately hemorrhages under the skin occurred around the area of incision. Bleeding, although slight, was almost continuous. Every diaper removed was bloodstained. Within a few days after operation numerous subcutaneous hemorrhages were noticed on various parts of the body. Compresses were used to the wound, calcium lactate, and later, calcium chloride were given by mouth. The case was referred to the Division of Pediatrics at this time. Horse serum was given subcutaneously and intramuscularly, with no effect, either on the coagulation time, or on the hemorrhages. Transfusions were given intraperitoneally, using both the mother's and a male cousin's blood. Blood from both the mother and the cousin were given intramuscularly. The patient started to bleed profusely from the urethra, and the transfusions were continued almost daily. A cystitis developed and large quantities of sodium citrate were given by mouth. None of these measures seemingly had the slightest effect on the bleeding.

At this time the fact was obtained from the parents that for the last six months the infant had bruised very easily, and that every bruise was followed by a small lump under the skin, which later became discolored. They stated that even the mere shaking of the infant at times caused these bruises to appear. All of the evidence obtainable pointed to this being a true case of hemophilia. No family history of the condition was obtained. The only other male member of the family known, who would be in the possible line of descent, was one brother of the mother, and he had given no history as a bleeder. In addition to the history of what were probably numerous subcutaneous hemorrhages continuing over a considerable length of time, the continuous bleeding from slight wounds, and from the urethra, the following tests seemed to confirm a diagnosis of hemophilia. There was a markedly prolonged coagulation time; the bleeding time was always normal; the tourniquet test was negative; the platelet count was normal; all of the clots passed from the urethra and those of the blood drawn from the heel were retractile in character.

On July 8th the hemoglobin was thirty per cent Sahli. The child had bled almost continuously for six weeks, during which time various efforts had been made to control the bleeding. He was probably kept alive only by the repeated transfusions. At this time tissue fibrinogen was given by mouth, in ice water, on an empty stomach. The dose was fractional, 1.5 cc. of fibrogen, (0.0075 Gm. of purified tissue fibrinogen) being given at two hour intervals for 4 doses. The coagulation time up to this period had varied between twenty minutes and over forty-five minutes. At the time the first dose of fibrogen was given the clotting time was over fifteen minutes. Thirty minutes after the first dose it was eight minutes, and thirty minutes after the third dose it was five minutes, which was lower than it had been at any time. No more clots were passed from the urethra. The amount of the bleeding was at once greatly diminished, and ceased altogether the next day. The coagulation time remained lowered all the next day, but a week later was back to thirty-five minutes. No further bleeding from the urethra occurred. One week after the first dose the same amount was again given in the fractional doses. At this time the coagulation time was over forty-five minutes, there was no bleeding, and the fibrogen had seemingly no effect on the time of coagulation.

Case II.—A. B., a boy, aged twelve. At the age of nine days this patient had been circumcised, bled very profusely, and was diagnosed at this time as a bleeder. Since infancy he had bled easily and long, at every slight cut, and every bump caused a hemorrhage under the skin. At two years of age he had a hemorrhage into his right ankle, and since then other hemorrhages frequently at the slightest injury to his joints. These involved both ankles, both knees, both elbows, and occasionally the finger joints.

At the time of entrance to the hospital in June 1926, he was suffering from hemorrhages into the left knee and elbow, which had started ten days previously. He was complaining of very severe pain in these joints.

There was marked pallor of skin and mucosæ. The right elbow joint was deformed, motion was limited, and it was somewhat tender. The left elbow joint was swollen and tender, and fluid was present. The right knee was swollen and tender, with ecchymotic areas over the patella. The left knee was very much swollen, very tender, and contained fluid. Röntgenograms showed areas of bone destruction near the articular surfaces of both humeral condyles, under the trochlear surface of the ulna, and in the articular surface of the left patella.

The hemoglobin was fifty per cent Sahli, with 2,750,000 red blood cells; white blood cells were 9,600 with a normal differential; platelets numbered

*From the Division of Pediatrics, Stanford Medical School.

381,000; the bleeding time was one and one half minutes and coagulation time twenty-five minutes; the clot was retractile in character, and the tourniquet test was negative.

Sedatives and hot compresses were given the first three days. The circumference of the joints became slightly reduced and pain was somewhat alleviated. On the fourth day the size of the left elbow began to increase, and was very painful. The coagulation time was twenty-five minutes at the time tissue fibrinogen was administered. It was given in doses of 3 c.c. of fibrogen, (0.015 Gm.) in ice water, on an empty stomach. At five and ten minutes no change in the coagulation time was found; twelve minutes after giving, the clotting time was thirteen minutes; after fifteen minutes the time was ten minutes; twenty-five minutes after administering, a firm retractile clot formed six minutes after withdrawing the blood.

No further swelling of the joints occurred. By the next day pain had ceased, and tenderness gradually subsided. Four days later, with no hemorrhages occurring, the same dose was given under otherwise the same conditions. The coagulation time was now over forty-five minutes, and no apparent effect was obtained by giving the fibrinogen tissue extract.

CONCLUSIONS

1. In two cases of hemophilia tissue fibrinogen, given by mouth, in ice water, on an empty stomach, exerted a very decided effect on the bleeding coincident with a marked reduction in coagulation time of the blood. In these cases the bleeding was checked for the period of observation, although the coagulation time was reduced for only a few days at the most.

2. Since the bleeding in hemophilia is difficult to control by other methods the use of tissue fibrinogen by mouth deserves further trial.

The Principles in the Treatment of Cancer*

RICHARD J. BEHAN, M.D.
Pittsburgh, Pa.

(*Continued from page* 471)

That such an operation is without danger cannot be said. Deaths do occur and it is just the class of patients in whom the benefits are the greatest that the mortality is the highest. Its risks are counterbalanced by the relief it brings to the patient and the enhancement of his chance for cure. As I stated before, in cancer of the uterus, limitation of the blood supply is of value. Both internal iliac arteries are tied a short distance from their point of origin. I have never noticed any ill effects from such ligation. There is an immediate lessening of bleeding and it may entirely cease. Hysterectomy in such patients is, however, not made entirely bloodless. Bleeding is reduced to such a degree that extensive operative manipulation is rendered safer. In cancer of the rectum, ligation of the inferior mesenteric artery may be undertaken.

The supposition that lessening of the blood supply is advantageous in cancer therapy is supported by the opinion of many investigators.

Carter Wood evidently believes that good blood supply is essential to the rapid proliferation of cancer cells, for he says in speaking of the immobilization of the cancer cells in scar tissue that—"the dense scar tissue immobilizes the cancer cells and the diminution in blood supply prevents their rapid growth." He further states—"when the tissues are excised and a large amount of blood is furnished the tissues, as healing takes place, they are then capable of renewed growth." He also attributes the death of cancer cells in a square bounded by radium needles to be due to thrombosis of the vessels with an insufficient blood supply, so that they are destroyed by a dose of radium insufficient to destroy other cancer cells, not so ill nourished (2). Knox, discussing epithelioma of varicose ulcers, states that in this lesion, where irritation has been present for a number of years, cancer does not develop. Here the blood supply is extremely bad. Knox (3) further states, "if the blood supply is adequate, a carcinoma will grow faster when once formed." Lumsden (4) states that rat sarcoma of the foot can be made to disappear by repeated injections of antiserum, into and around the tumor, with *temporary stoppage of circulation in the foot.*

It is also quite possible that the limitation of the blood supply renders carcinoma tissue more susceptible to x ray and radiation; at least it does not render it less susceptible.

Under surgery should also be classed the electric and the coagulating methods of treatment. These include fulguration and diathermia. Fulguration is nothing except the concentration of heat at a point where a small electrode comes into contact with the tissues. It is extremely useful in carcinoma of the external surfaces of the body and has also been used in the bladder and other hollow cavities. Diathermia, which is electrical heat, is useful in treating somewhat wider areas where it is necessary to bring the tissues to a high degree of heat, so that in reality cooking takes place. The electric energy passes through the tissues in parallel waves, provided the tissues are of homogeneous density. If there is a variation in density, the rays pass through the tissues of less density more easily than through those of greater density.

*Read before the Buffalo Academy of Medicine, November, 1925.

They also tend to concentrate from a larger electrode to a smaller one, so that it is fairly easy to plan a diathermia attack upon a diseased area.

A very interesting experiment has been made, showing a possibility of utilizing diathermia in treatment. Paramecium, which are unicellular animals, were exposed to radiation. It was then discovered that they were destroyed by a much lesser degree of heat than would be the optimum for their existence. They were destroyed by 17 to 18° C., while their optimum temperature was 24 to 28° C. If the same biological reaction occurs in cancer cells as in these unicellular animals, and they are sensitized to heat the same as are unicellular animals, then, after a preliminary raying, the cancer tissues will be destroyed by a lesser degree of heat than is ordinarily restructive to healthy tissues. For this reason we are now experimentally using diathermia after x ray treatments.

TREATMENT OF CANCER BY IRRADIATION

There is quite a difference of opinion as to the effect of radiation upon cancer cells. As Bovie and Hughes state, the rays may act by interfering with the process of metabolism, especially the inorganic salt metabolism, or may act directly upon the mechanism involved in cell division, retarding the rate of such division. The electrons proceeding from the vacuum x ray tube penetrate the cell and disrupt some molecules, while other molecules are not disturbed. If the molecules which are involved are vital for the function of the cell, the cell is destroyed, while if they are not, the cell lives but has a much reduced vital activity. Sometimes it seems that small doses of x ray may also be stimulating to cell division.

Bovie's theory of the effect of radiation is that the cell radiation produces changes in the protoplasm in which photoproducts are formed. These photoproducts act as a toxic poison upon the unaltered cell protoplasm and produce altered sequence in metabolic changes.

Radiation also disturbs the colloidal equilibrium of the cells with consequent devitalization (Sternstrom). The period of cell division is the time of greatest sensitiveness to x ray, as stated by Perthes in 1903. Bohn in 1904 attributed to the chromatin, the radiosensitivity of a cell. Holzknecht predicates his fractional deep therapy treatment of cancer upon the fact that a single radiation can only destroy the cells which are in mitosis at the time of the radiation and for this reason, it requires successive radiations to destroy the cells as they successively come into mitosis, or cell division. In a testis, ovary or thymus sterilized by x ray, there is no evidence of any vascular change or effect upon the connective tissue, so that the effect in such action must be upon the functionating cells. Again apparently fundamentally contradicting this, are the experiments of J. B. Murphy and others in which a spontaneous tumor of a mouse was removed and divided into two parts; one was given an erythema dose of x ray; each piece was now innoculated; each piece grew equally well. The untreated graft was then given an erythema dose which *included the surrounding skin;* the tumor promptly disappeared in thirty-eight out of fifty mice.

Spontaneous tumor removed, divided, inoculated; one of the grafts, after it had taken, was rayed, removed and inoculated. In seventy-nine per cent. the rayed tumor grew well.

Some regard the beneficial results from x ray as due to a large extent to substances produced by changes in normal tissues, induced by the x ray and not so much to any direct action upon the cancer cells (6). Kok, F. (7), found that more retrogression occurred when the entire animal was rayed than when only the tumor area was rayed. Rigaud holds that the cells are not directly acted upon by the rays but are poisoned by a substance liberated from the plasma or from the collagenous substance in which the cells lie. Ewing also believes that "the reaction of the tissues is an essential factor in the curative process." Portis (10) states that the röntgen rays have a stimulating reaction upon the normal protective forces of the body, or that they produce changes in the tumor tissues which stimulate the phagocytic activity of the adjacent tissues." It may be that radiation produces disintegration of the treated cells with liberation of a chemical substance which has a stimulating action upon the surrounding tissues. It is also held that radiation has a stimulating action upon the enzymes. *The fact that there is such a variety of opinion upon the effect of x ray upon cancer tissue, indicates that the action is as yet imperfectly understood.*

However, it may be regarded as definitely settled that the effect of x ray upon a tumor varies with its histological structure, with its position in the body and the particular time at which it is attacked. It seems that sarcoma and those tumors which are of glandular origin are affected to a greater degree by x ray than are the tumors of other cell types. The more superficial the tumor, the less the intervening tissues, the greater is the action of the x ray upon it. There seems to be also particular times at which the x ray has greater effect upon tumor tissues, than at other times.

The x ray also has an action upon the tissues surrounding a tumor, in that it produces degeneration, as is thought, of the endothelium; and the vessel wall becomes infiltrated with leucocytes. Proliferation into the lumen of the bloodvessel walls occurs, so that a thrombosis takes place with consequent anemia of the cancer tissue. This interferes with the growth of the tumor (Woglom, Ewing and Armstrong).

It should also be remembered that the x ray has constitutional effects. In sufficient doses and with long enough exposure, it causes an anemia of the person who is subjected to it. In some persons this anemia seems to be a factor in increasing the malignancy of the cancer. Also by some other and constitutional change, the x ray seems to reduce the resistance of the patient, so in such instances, the malignant growth spreads very rapidly. Great care should be taken in such cases in the application of the x ray as a therapeutic measure.

The x ray is extremely beneficial and curative for cancer upon the surface of the body. In such cases a cauterizing dose should be used; that is, sufficient dosage should be given to destroy the pernicious cells. This requires two or three times, even four times, the ordinary erythema dose. The action of the x ray here, as well as the action of radium, is that of a cautery. Any less dosage, according to the workers

in this field, is not beneficial. If the first dose is not destructive, the tumor cells frequently acquire an immunity against the x ray, so that subsequent treatments with it are useless. This we have seen exemplified in many cases at the Pittsburgh Skin and Cancer Foundation, where it has been necessary after repeated and long continued treatment by x ray and radium to do a radical excision of the growth. In some cases, after x raying the tumor, the cancerous tissues should be removed by surgical means, as potentially they act as a focus for reinfection and reproduction of the growth. Removal may in some cases be made by the cautery. In every instance, it should be as thorough as is possible.

Apropos of the treatment of skin cancer it is significant that over eighty per cent. of basal cell cancers are cured. It is rather more difficult to treat the prickle cell carcinomata, especially those of the cervix and of the mucous membrane, than it is to treat the basal cell type of carcinoma. These cases should be treated by direct implantation of radium or by excision. It seems to make no difference whether the adjacent lymph glands with their surrounding fascia are removed primarily or secondarily to the removal of the carcinomatous lesion. In removing a carcinomatous lesion, pressure should not be made upon it and care should be taken not to open up adjacent lymph pathways, even though the fascia and lymphatic tissue through which the gland drains have to be removed by a prior operation.

Hazen and Whitmore find that of basal cell cancer, only fifty per cent. of cures resulted when they had cases which had previously been treated with röntgen ray or radium. Only forty-five per cent. of prickle cell cancers were cured and forty-one per cent. of gland cancers.

Before irradiation, the blood should be examined and if the patient is anemic, especially if the anemia is severe, a transfusion should be done. An attempt should be made by the radiotherapist to so regulate his treatments that leucopenia does not result. Those cases not showing leucopenia (Minot and Swelling) and showing an increase of lymphocytes (Murphy) did the best.

SENSITIZATION TO X RAY

Webster believes that preliminary ionization with copper selenate may sensitize to x ray. Galvanic current also has been used by Wintz for the same purpose. It has been found that after passing galvanic current through the lower portion of the abdomen, so that it encounters the uterus, that the radioactive effect of x ray or radium is greatly increased.

Cachetic individuals, i. e., those with very low resistance and low blood pressure and low blood count, should not be given x ray treatment; nor should those in whom the disease is too widespread or metastases are present and are diffused, especially in cases of ovarian tumors of a malignant nature in which the metastases are spread throughout the entire abdomen and in the pelvis.

CONSTITUTIONAL TREATMENT

The second active division of treatment is the constitutional treatment; that is, the attempt to influence the growth by changes in the body itself—either by introduction of drugs or organic substances, by diet, by stimulating the protective, reactive processes of the body itself against the cancer by serums, extracts, vaccines, etc. The first requisite of cancer therapy is to put the cancer patient in the proper attitude toward his disease. The question frequently arises, should we tell a patient suffering from cancer what is his trouble. I think the answer depends particularly upon the type of person whom we are treating. If he is of the nervous, apprehensive, fearful type, I believe that it is well for us to procrastinate in telling and gradually allow the knowledge of what is wrong to enter the consciousness of the patient. For the time when this knowledge becomes definite and he realizes the full import of his condition, he should be prepared by suggestions that cancer can be cured, that in its management and control many advances have been made. To support this belief of the patient, active therapeutic measures of one type or another should always, in every case, be persistently continued; for it is to these measures of relief that the patient clings with steadfast purpose and hope for cure. Fast desire for betterment is a therapeutic measure that should never be neglected by the physician. In this respect all causes for worry should be taken away. No mental anxiety should be permitted; all disturbing efforts should be avoided.

Sir Astley Cooper recognized the disturbing influence of mental unrest upon a cancer patient, for in speaking of the breast scirrhus, he says: "the disease is made up of a derangement of the constitution and of a peculiar local action. I should have observed just now, when speaking of the cause of the complaint, that one of the most frequent is grief or anxiety of the mind. It averts the progress of the secretions and other conditions. How often have I seen, when a mother or nurse has been watching night after night, that in a short time after this, she has come to me with an uneasiness in the breast, which on examination I discovered to be scirrhus. Look, then, in this complaint, not only at altering the state of the constitution, but relieve the mind and remove the anxiety, if possible."

A cancer patient should be allowed to husband his resources to fight a most desperate battle. He should be given good food, good air and good surroundings. Every attempt should be made to keep up the patient's weight, because starvation causes an acidosis and further it has been found that tumor cells can and do utilize the tissues of their host when there is nutritional deficiency so that starvation of the host acts as a boomerang to his own undoing. The bowels should be kept free; elimination should be active.

In cancer, as there is usually an acidosis, the alkalinity of the blood should be estimated by frequent examination and determination. All the emunctory organs of the body should be active.

DIET

It is very difficult to define the action of diet upon cancer. The intake of food by the host does not seem to have any influence upon the rate of growth of cancer cells. For cancer acts in the same way as does the fetus in utero and will continue to grow despite the fact that its host is dying of starvation. It has been found that the diet which produces restriction of somatic cell growth is the one that increases cancer tumor growth. It is also found that cholesterol in

transplanted growths has a stimulating action upon the tumor growth and its metastases. Deprivation of food does not seem to have lowered cancer mortality as is shown by the prewar and postwar statistics of any European city.

That the character of the food may have some influence upon cancer growth may be indicated by statistics of the Chicago Board of Health which show that the percentage of deaths from cancer among emigrants from Oriental countries and native Americans was much less in proportion to number than among Germans and immigrants from Eastern Europe. It was found on studying the diet of the Orientals, that they did not eat meat and that the Americans ate very little; while other nationalities ate large quantities of flesh. This seems to corroborate, in a small way, the contention of those who hold that a meat diet is harmful in patients suffering from cancer.

However, this idea is again controverted by the experimental work of Fugiura and Benedict, who from a series of tests on rats and mice, conclude that "the malignant character of cancer cells cannot be influenced by the ingestion of high protein or protein free diets or high carbohydrate or low carbohydrate diets."

SODIUM BICARBONATE IN THERAPY

Of the production of an alkalosis as a means of cure or prevention, it has been found that cancer always produces a lactic acid increase in the blood. C. F. Cori and G. G. Cori of Buffalo, in their study of carbohydrate metabolism of tumors, found that if a tumor were growing on one wing of a chicken, the blood which passed through the tumor contained on an average twenty-three milligrams less sugar and 16.2 milligrams more lactic acid than the blood which passed through the tissues of the normal wing. The plasma obtained from the blood on the tumor side showed with such rate of metabolism 3.7 per cent. less of carbon dioxide than that of the normal side. A plasma blood that had been collected under oil, gave as an average only .7 volume per cent. less of carbon dioxide when compared with that of the normal side.

In addition to the above is the fact that Blumenthal and Frau Rhoda Erdman were not able to grow cancer tissues artificially, unless they added to the media, small quantities of lactic acid. In other words, the media in which the growth occurs must be acid. It is also a pertinent fact and should give us pause for study, when we observe the alkalosis which is produced by deep therapy on the treated cancer area. The alkalosis, according to the researches of Doub and others, is most intense at the point where the deep röntgen rays would be most concentrated and gradually becomes less toward the periphery of the growth where the concentration of the rays would be less.

From this fact it might seem possible that the beneficial effects of röntgen ray therapy may in some way be due to the production of alkalosis in the tissues, so that the cancer cells, localized in that tissue, are not able to receive the normal stimulating substance, the socalled argusic or autoxic principle which stimulated them to uncontrolled reproduction.

However, the conclusions which might be formed from these experiments are not to be formulated except through a mass of somewhat contradictory evidence. It has been found by Warburg (12) "that glycolysis is the factor supplying the reaction for growth. The splitting of carbohydrate into lactic acid (in which Meyerhof and Hill see the source of energy for work) may furnish the driving forces for growth." "From experimental work" (Warburg concludes), "there is no growth without glycolysis." Warburg (12) also believes that the causative factor for growth in tumors is an oxygen deficiency.

It is Warburg's idea that in oxygen deficiency (produced by pressure, sclerosis, action of bacteria and other influences) certain cells which are not able to glycolyze, die; those able to glycolyze, live. In other words, the cells able to live, utilize energy set free by the glycolysis and grow at its expense. The lactic acid presence gives the cells the stimulant or urge for growth.

It was likewise a potent fact that when the glycolytic power of tumor tissue is destroyed, as by freezing with liquid air, the tumor tissue cannot be transplanted. Therefore, glycolytic activity is an integral part of the tumor cell. Human carcinoma produces under anerobic conditions sixteen per cent. of its weight in lactic acid per hour. This is three or four times as much per hour as benign tumors produce.

A peculiar fact is noted in this work of Warburg's and that is, that bicarbonate in increasing concentration with a constant Ph produces a constant increase in acceleration of glycolysis. If bicarbonate solution is not in the Ringer solution in which the growth has been produced, there is only a slight degree of glycolysis. We notice that he keeps the Ph constant, so that there is in reality no increase in the alkalinity of the tissue. In the treatment of cancer we are attempting to apply certain conclusions derived from the mass of data given above. At present we are giving certain of our patients alkalies so that the Ph concentration is about 7.3 or less. Frequently the patient tests the reaction of his urine and takes sufficient quantities of bicarbonate to keep it constantly alkaline.

We have observed the following phenomena: the growth seems at least temporarily subverted; the patient's appetite increases; pain is lessened and temporary wellbeing results, with increase of weight and better mental attitude of the patient toward his disease. However, he cannot long continue with heavy doses of bicarbonate as it destroys his appetite. We have tried giving it in capsules, which is some slight improvement over the older method.

DRUGS

Many attempts have been made to influence cancer through the use of substances introduced through the circulation. The nuclei of cancer cells stain deeper than do those of normal tissue. Wassermann thought that if he could combine a nuclear poison with a nuclear dye, the dye would probably carry the cellular poison into the nucleus and thus produce cell death. For this purpose he combined the selenate of copper with eosin and introduced it intravenously. The amount of the drug necessary to produce cellular death was so great that about seventy per cent. of the animals (rats and mice) upon which it was tried, died. As far as I know, no attempt was made to treat human subjects with this remedy.

(To be concluded)

Instruments, Apparatus, and Clinical Notes

The Homigrade Thermometer

F. E. ASPINWALL, M.D.

Miami, Florida

Why a new thermometer scale? Is not the Fahrenheit good enough? And is not the centigrade perfect? "Come, let us reason together" in order that we may arrive at correct conclusions regarding these matters.

That the Fahrenheit scale is absurdly unscientific is conceded. Its zero is nowhere of consequence, and does not serve to separate important values. Hence its every figure is a misfit, and is misleading as to values. It fails in the one great purpose of figures which is to impart a realizing sense of values.

That the centigrade degree is too long for ordinary precision, as in weather reports, without constant resort to fractions is selfevident. In this case the fractions would be burdensome. In the centigrade clinical thermometer the degrees and tenths are two and seven tenths times as long as are those of the homigrade thermometer, which has the shortest degrees of all and is therefore the most precise with or without fractions. Moreover, the centigrade figures give no realizing sense of the values for which they stand because of the want of a suitable figure to express the human normal, which is the only point from which values can be clearly realized. This idea is appreciated only when it is known that man has a very intimate knowledge of his own normal within the radius of his sense of heat, and that he consciously or unconsciously measures all temperatures as sensed by comparing them with this normal, which is his criterion of temperature values. In the making of a thermometer it is not wise to ignore the nature of man. He may use an instrument thus out of harmony, but it can not be wholly satisfactory.

There is no reason why the numerals of a temperature scale should not express values as clearly as do those of any other measure. This is a reasonable requirement which is met completely only by the homigrade scale. And it is in line with the nature of man. It aids man in his natural tendency to measure all temperatures by comparing them with his own normal, and it reduces this natural system to scientific accuracy. It, in fact, expresses every temperature as a percentage of the human normal. And this is only half. The other half is a definitely understood measure from the vital heat zero, the point between freezing and thawing. A thing that is perfect so appears from every angle and in every detail. Let us see if the homigrade scale so measures up.

In the homigrade scale zero is at the point without dimension between freezing and thawing, which in this system is called the vital heat zero, because even in the hardiest of organisms or parts thereof this point marks the complete cessation of vital action, functioning being resumed, if possible, only after a sufficient rise in temperature. The least fall in temperature below this zero causes a congelation of their fluids which destroys some organisms. Life is destroyed in some others before 0° H. is reached.

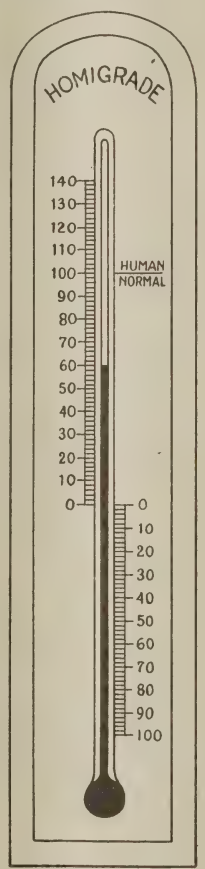

FIG. 1.—The homigrade thermometer.

When a thermometer tube is placed in the coldest of pure ice water and marked for the freezing point the point thus marked is very close to the zero between freezing and thawing. The water is not at the freezing point. If it were it would be frozen. An imperceptible variation from this zero is either freezing or thawing. Thus it is understood why these three points, freezing, zero, and thawing, have been regarded as one point. Freezing is below the zero; thawing is above it with no measure between, just as there is no measure between a piece of ice and the water in which it may be placed. This is the only true zero in the temperature scale, all other points being measures from this point. In the economy of nature it is the true point of division between heat and cold. Receding from this point both heat and cold become more intense. On one side there is life, and conscious activity. On the other side there is complete suspension of vital action. Hence is seen the propriety of measuring vital heat from this zero 0° H., which is the lower fixed point of the homigrade scale.

To express the standard boiling point of water in the homigrade scale the figure 270, which, by the way, contains even nines, was chosen because of consequent ideal figures at other important points in the scale, especially 100 at the human normal, or full vital heat within the radius of common sensation. This point is one tenth of a homigrade degree above 98.6° F. and 37° C. It has, however, been observed under the tongue, in the axilla, and even in the palms of the hands when there was full flush of heat and perfect health and comfort.

This scale therefore constitutes a new centigrade with its 100 mark at the human normal. Hence its degrees have each a value of one per cent. of the measure of this normal, and its every figure expresses not only a clearly understood measure from the vital heat zero, but also a true percentage of the human normal, which thus becomes the unit of value of the homigrade scale, corresponding exactly to the dollar in the United States money system.

This scale therefore is bimetric, furnishing instantly two measures or definitions of every temperature.

The four cardinal points of the homigrade scale are 100, 50, 0, and —50. They mark the human normal, separate the seasonal temperatures, and limit the normals of heat and cold. They are briefly described as follows:

100° H. human normal. The full vital heat within the radius of common sensation, a measure of one hundred homigrade degrees from the vital heat zero. The unit of value of the homigrade scale. The limit of normal summer heat, above which is extreme heat.

50° H. The point between spring and summer, and summer and fall temperatures. An ideal atmospheric temperature for active work or play in moderate clothing.

0° H. vital heat zero. The zero between freezing and thawing, and hence between winter and spring, and fall and winter temperatures. Point of separation of positive and negative values.

—50° H. Limit of normal winter cold, below which is extreme cold. Note that seasonal temperatures are not determined by the calendar, but by their measures from the vital heat zero. They are best exemplified in the temperate zones.

Thus is seen the most ideal exposition of the seasonal temperatures with lines of demarkation so fitting and appropriate that they can not be forgotten.

The clinical section of the homigrade scale is from 85 to 115, which includes the normal and 15 degrees of departure both above and below, these being the usual limits of departure compatible with life. Every body temperature is expressed as a true percentage of the human normal, thereby giving a concept of values that would be otherwise impossible. The following table is offered as an aid in the study of body temperatures:

HUMAN NORMAL

100° H.

Subnormal		*Supernormal*	
95° H.	moderate safe	105° H.	moderate safe
90° H.	low dangerous	110° H.	high dangerous
85° H.	very low usually fatal	115° H.	very high usually fatal.

Here again the homigrade figures are ideal and so fitting that they are memorized in a minute and never forgotten. Equally ideal are the homigrade figures that express the usual bath temperatures, as here shown: Cold, 50° H. Very cool, 60° H. Cool, 70° H. Tepid, 80° H. Warm, 90° H. Normal, 100° H. Hot, 110° H. Very hot, 120° H.

Ideal indoor temperatures range from 50° H. to 60° H., which range includes the first ten degrees of summer heat. There is usually neither chilliness nor overwarmth within this range, but departures either above or below are likely to cause more or less discomfort indoors.

There is but one point in the two scales where the homigrade and Fahrenheit figures are identical, 96 expressing the same temperature in both scales. Receding from this point their figures become increasingly different according to their ratio of 1.5 to 1. This incidence results in a close similarity of the figures used in these two scales to express high summer temperatures. Hence in adopting the new scale nearly all summer temperature figures will seem familiar. A noteworthy coincidence is that this figure 96 expresses the highest temperature ever recorded here in Miami by the United States Weather Bureau. As to temperatures near freezing, as in spring and fall, it is always desired to measure them from that point. Here the homigrade thermometer furnishes the desired information at a glance and in terms that are instantly understood. And it is a pleasure to note the existing temperature and realize at once its value and the season to which it normally belongs.

In the homigrade thermometer all figures above the zero express positive values and are placed to the left of the tube. All figures below the zero express negative values, and their position is a perfect reminder to not omit the minus sign when using any of them. Thus the positive and negative values are clearly separated as are assets and liabilities in accounts.

With the perfecting of the scale it was a surprise to find that the ratio of the homigrade degree to the Fahrenheit is exactly 1.5 to 1, and to the centigrade 2.7 to 1, thus rendering conversion of the scales an easy matter. Hence to convert Fahrenheit to homigrade multiply the exact Fahrenheit measure above or below freezing by 1.5, and to convert centigrade to homigrade multiply by 2.7. The process is reversed to convert homigrade to either of the other scales. The ease with which conversions are thus made renders the adoption of the new scale an easy matter, and one not attended with any confusion whatever, in fact with satisfaction only. It will be found a pleasure to convert the practically meaningless figures of other scales, to homigrade and thus cause their values and interrelations to appear as the rising sun.

The homigrade system of temperature measurement appeals to reason, and satisfies the desire to know. It so expresses temperatures that they are at once understood from each of two different angles. Its every figure has two distinct meanings that go direct to the understanding and satisfy it completely. With its other distinctive features there is nothing more to be desired. Moreover, it is world owned[1], and not a monopoly.

The Electrocardiogram in Myocardial Insufficiency.—A. Clerc and R. Lévy (*Presse médicale,* March 27, 1926) lay stress on the prognostic importance of records in which the waves are flattened or broadened to such an extent as to constitute only small oscillations above or below the isoelectric line. Pathology has supplied no decisive evidence in favor of aborization block as the cause of these manifestations, which are better accounted for by myocardial fatigue.

[1] A few homigrade thermometers have been distributed in some of the principal cities of the world, but the writer has no instruments for sale. Should the reader desire to have any made by his favorite instrument maker, the writer will without charge furnish all needed specifications.

A Device for Facilitating Digital Examination of Rectum

J. F. MONTAGUE, M.D., F.A.C.S.
New York

In these days of periodical health examinations complete physical examinations are being made in daily increasing numbers. As a matter of thoroughness a rectal examination is included in the routine and usually consists in a digital examination. Although the method has limitations, yet there is no doubt as to its field of usefulness. It is very simple, of course, in its technic and consists of palpating the tissues of the anal canal, the rectum, and their pelvic neighbors, with the index finger.

Decency, of course, demands that the finger and hand be protected from soiling and this requirement is usually met by the use of a rubber glove. However, employment of the rubber glove has distinct disadvantages, chief among which are the impairment of the tactile sense by the thickness of the rubber imposed between the skin of the finger and the tissues palpated. Then, too, there is the likelihood of tearing the glove in the process of putting it on and taking it off—the labor of cleaning individual glove fingers, and finally the actual cost of the glove.

Heretofore, these two chief disadvantages of the rubber glove have been overcome in the following manner: The use of a finger guard consisting of a circular piece of rubber, in the center of which one finger has been cemented, has successfully overcome the disadvantage of difficulty in cleaning, and then the smaller likelihood of being torn has proved them to be more economical than gloves. There is still, nevertheless, the objection of an interference with tactile sensibility. The latter disadvantage is usually circumvented by the use of a thin tissue rubber finger cot, but when these are employed one must forego the hand protection afforded by the guard of the previously described device. If we attempt to have an entire finger guard made of this thin rubber, we find that we have an extremely fragile affair which tears very readily and is expensive because of the constant need of replacement.

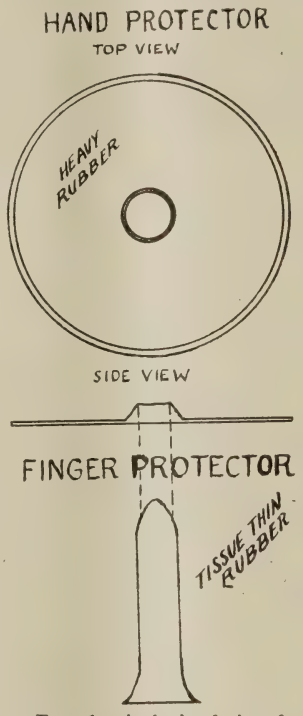

Fig. 1.—Author's device for facilitating digital examination of the rectum.

For some time past I have been using a device which has proved very practical and serviceable and one which I believe combines the advantages of both the finger guard and the finger cot. Briefly, it consists of a circular shield of heavy rubber eight inches in diameter with a central aperture just a little smaller than will admit the average index finger. This serves to protect the hand from soiling. The second part of the device consists of a thin tissue finger cot. This acts as a protector to the finger.

It is readily apparent, therefore, that by this combination we have an ideal arrangement for digital examinations, since we are afforded the utmost in tactile sensibility and yet do not have to forego the protection of the shield. The shield is easily cleaned and lasts indefinitely. The cots are easily replaced and when torn their replacement is a cheap procedure.

No doubt this arrangement has occurred to others but I have never seen it used and being convinced of its advantages take this opportunity to suggest its use to any who have occasion to make rectal examinations.

540 Park Avenue.

Methods of Staining Tubercle Bacilli.—H. J. Corper (*Journal of Laboratory and Clinical Medicine*, March, 1926) examined twenty sputum smears containing tubercle bacilli by thirteen staining methods. With properly performed technic the majority of these methods result in staining the tubercle bacilli in the sputa with equal efficiency, but with a decided difference in the ease of performance, speed, and simplicity of the various methods. Sixteen different positive sputum smears consecutively stained and restained (after destaining) by nine different methods (Ziehl-Neelsen, Andrejew, Herman, Konrich, Gasis, Fontes, Burke and Dunning, Ehrlich, and Spengler) emphasized further the importance of technic in the staining of tubercle bacilli. Much's (Gram) method alone proved unsatisfactory with sputum on account of the difficulty of differentiating tubercle bacilli from other small cocci and dye precipitates, since in the majority of cases only the granules stain. Double bacillary staining (carbolfuchsin—Gram-Much) of sputum and pus did not increase the efficiency of the simple single bacillary (carbolfuchsin) stain but increased the cumbersomeness of the technic. For practical purposes the simpler methods have the advantages of speed and simplicity. The finding of acid-fast bacilli (with the usual clinical precautions) practically certifies a diagnosis of tuberculosis by the simple methods, while the presence of Gram (Much) granules alone requires corroborative positive animal inoculation findings to certify the diagnosis. It is for this reason that the Gram (Much) granules and combined methods are mainly of academic interest. It does not seem that the Gram granules differ from the granules seen in appropriately stained carbolfuchsin preparations since their numbers, morphology, and location appear to be identical. Preparations stained first by the Gram (Much) method followed by the modified Ziehl-Neelsen carbolfuchsin-acid alcohol technic reveal only blue granules in a red bacillus.

The Epileptic Convulsion as a Type of Extrapyramidal Motor Disturbance*

LELAND B. ALFORD, M.D.

St. Louis, Mo.

As is now well known the extrapyramidal motor disturbances are due to lesions involving the corpus striatum, substantia nigra, red nucleus, and perhaps other cell groups situated at the base of the brain. The best known of these disturbances are chorea, tremor and athetosis but to these may now confidently be added torsion spasm and myoclonus. In the present article it is the contention that the epileptic convulsion is also an extrapyramidal disturbance.

The extrapyramidal disturbances are produced by any manner of lesion that affects the nuclei mentioned. But here we shall direct attention to that pathological process which consists of a selective degeneration arising on a basis of innate weakness and is designated, following Gowers, abiotrophy. The conditions that depend on this process are the progressive muscular atrophies and dystrophies, Friedreich's ataxia, Huntington's chorea, otosclerosis and the like.

For some years I (1) have been interested in the process, abiotrophy, because of its possibilities in elucidating some of the dark corners of neurology and psychiatry. Its selective attack and microscopical appearance are best understood by considering progressive muscular atrophy and Friedreich's ataxia. In many of the conditions the lesion has not been demonstrated, for instance, Huntington's chorea and paralysis agitans, but can safely be subsumed to exist by analogy and general considerations. The total number of the abiotrophies is about fifty. A majority of them are quite rare but if epilepsy and dementia precox are eventually found to be abiotrophies, they will constitute the most important group of conditions in all medicine.

The abiotrophies have received but scant attention as a group. This neglect seems to arise partly from the fact that neurologists in general and authors of text books in particular have been more interested in nervous physiology than in pathology, and partly from the obscurity of the various types, which necessitated concentration in research on one form. The consequence of this situation is that the process, abiotrophy, is little understood, but in recent years German workers (2) are showing increasing interest. Apparently the process is essentially the same in all the abiotrophies, the symptoms of the different types depending on the structures where the process happens to centre. It is the localization, not the process, that is specific.

This being true we can erect the abiotrophies in a sort of graded series and by studying the series as a whole derive many instructive conclusions in regard to individual members.

Epilepsy is included among the abiotrophies by virtue of the clear influence of heredity, the postnatal onset, and the progression which is evidenced in the mental deterioration.

There is some difference of opinion, it may be said, in regard to the origin of the mental deterioration of epilepsy. It has been ascribed to the use of bromides, to the exhaustive effects of the attacks and to mental conflicts; and no doubt these all contribute to accentuate it. But all facts considered, the most plausible conclusion seems to be that of Turner (3): " . . . the mental condition (deterioration) is not solely a consequence of the seizures but is an expression of the same nervous constitution which gives rise to the convulsions." It would seem that workers in epilepsy have not accorded sufficient significance to the mental symptoms. Being permanent, one would judge that they are a better index of the pathological process than the more spectacular seizures. We would, therefore, conclude that the progressive mental deterioration is an indication of a progressive destructive process.

The extrapyramidal disturbances are all represented in the abiotrophies and, furthermore, often occur in combinaton with mental deterioration. For example, chorea occurs in Huntington's chorea, tremor in paralysis agitans, athetosis in progressive cerebral diplegia, torsion spasm in Oppenheim's dystonia musculorum deformans, and myoclonus in myoclonus epilepsy. Of these the first and last are characterized by marked mental deterioration.

In classifying epilepsy with the abiotrophies one, for obvious reasons, places it next these conditions

*Presented at the meeting of the National Association for the Study of Epilepsy, New York, June 7-8, 1926.

of which the symptoms are composed of progressive mental deterioration in conjunction with motor disturbances. To this arrangement the greatest scepticism will arise from the implication that the epileptic convulsion is in any way analogous to chorea, tremor, and the like. So it now becomes our task to consider this point more in detail.

II.

At first glance one gets the impression that the epileptic convulsion is essentially different from the extrapyramidal disturbances. Seizures except in the case of status are discontinuous while extrapyramidal disturbances are continuous. Again if seizures depend on a relatively stationary lesion, a second factor or factors must be hypothecated in addition to account for their initiation.

Still there seems no reason to conclude that continuity is an essential characteristic of extrapyramidal disturbances. These all vary with emotion and voluntary effort and all cease during sleep. Myoclonus, at least in the early stages, may show intermission. Thus other factors than the lesion influence the symptoms.

The idea of the origin of convulsive phenomena in infracortical mechanisms, furthermore, is not entirely novel. The Jacksonian attack has served to fix attention on the cortex in epilepsy; but as we shall see the cortical origin of Jacksonian attacks is not inconsistent with the conception herein supported. Despite the prevailing belief that the convulsion begins in the cortex, there has been for years, without any particular justification, a theory that the clonic component represents the activity of infracortical mechanisms. Then, too, cerebellar fits, socalled, and the tonic or postural fits of Wilson (4) have been accepted as having infracortical origins.

It is only within the last two years, however, that the infracortical origin of the epileptic convulsion is being discussed. Sterling (5) in 1924 in an article of which one part of the title is Remarks on Extrapyramidal Epilepsy, referred to spasmodic manifestations in epidemic encephalitis. For one thing he mentions the fact that he had previously advanced the suggestion that some attacks might be negative or paralytic. Now he wishes to add a third type of seizure, "extrapyramidal epilepsy."

Krisch (6) also in 1924, devotes to the subject two articles entitled respectively, Epileptic Motor Variations and Their Connection with Exogenous Hyperkinesia as well as the Extrapyramidal Symptom Complex and An Analysis of the Extrapyramidal Localization of the Epileptic Attack and Its Variations. In the first of these articles Krisch cites cases and discusses the occurrence in epilepsy of such motor exhibitions as chorea, tremor and clonus. He concludes: "The epileptic motor attack in the true sense (tonic-clonic attacks) as well as the epileptic motor variations (cerebellar, focal, dromoleptic and pyknoleptic [Schroder] syndromes) present stormy and quickly passing disturbances in the same structural systems which in the disorders with dystonic symptoms are affected more subacutely or chronically."

In the second article Krisch discusses the theoretical considerations of extrapyramidal attacks. He concludes: "By and large we may regard the generalized tonic attacks as an excited state of the motor tegmental system in which cerebellar, striatal and cortical regulation is broken down."

Last year Wimmer (7) of Copenhagen, under the title, Studies on the Extrapyramidal Syndrome, discusses striatal epilepsy and more directly refers to the possibility of seizures of an epileptic nature arising from lesions of the extrapyramidal mechanism. After describing a case in which torsion phenomena and a variety of seizures occurred together he asks the question, Is there a striatal epilepsy? This he answers: "I am led to believe there is." His evidence is, first, the occurrence of aberrant motor manifestations such as tremors, torsion, and choreic movements in cases of epilepsy and, secondly, the association of epileptoid and other tonic seizures with extrapyramidal syndromes in epidemic encephalitis. In two cases quoted from the literature autopsy demonstrated lesions located in the striatum. He also mentions the occasional noting of seizures in cases of Westphal's pseudosclerosis. In the conception of striatal epilepsy he sees no bizarre phantasy but only a variation in reactions and mechanisms which we now accept.

At this point it may be stated that I have under observation at the present time, in St. Louis, a family in which the mother and a son are afflicted with severe epilepsy while a daughter presents the typical picture of Huntington's chorea in a moderately advanced stage. Epilepticlike seizures in epidemic encephalitis are also seen by every neurologist at the present time.

The conclusions of the writers just quoted are all the more convincing since, although reached by another approach, they are identical with mine, which were reached by a consideration of the pathological process.

To me, however, the most convincing of all evidence has been entirely overlooked. This evidence is furnished by the entity, myoclonus epilepsy. Here in an abiotrophy in which mental deterioration is a marked feature, we have epilepsy intimately associated with an extrapyramidal disturbance. It seems strange that observers should not long since have perceived the significance for epilepsy of this association of symptoms. In discussing this disorder, although failing to derive any deductions in regard to epilepsy proper, Barnes (8) remarks: ". . . so the two marked manifestations may justifiably be assumed to have the same exciting cause and to reflect the irritability of the same regions of the nervous system."

It is true that myoclonus is not as constantly mentioned as an extrapyramidal disturbance as are some of the others; but still many writers so regard it and in an excellent critical review Pierce Clark (9) states: "In conclusion one may say that aside from myoclonia being a symptomatic accompaniment of various organic diseases more or less pronounced, it appears to exist solely in an ultramicroscopic lesion in the mid brain *per se;* an abiotrophy of the neostriatum or lenticular region between the corpus striatum and the globus pallidus is the most probable seat of the lesion in which the tonectic function of the neostriatum is affected."

Our conception that the specific causal factor in epilepsy is an abiotic degeneration affecting certain extrapyramidal structures presupposes the activity of nonspecific, exciting influences. Thus we may pic-

ture in our minds the extrapyramidal regulatory barrier containing a defect which is the consequence of the degeneration and over which to precipitate the convulsion floods nervous energy increased above the normal level. Any influence, then, which increases nervous energy—or tension or irritability or whatever it may be called—past a certain point can excite the individual fit. As exciting causes we can have a great number of factors, physical and mental. Even in the absence of defect we can conceive that sufficient augmentation may result in such overflow, as would likely be the situation in case of toxic and of Jacksonian convulsions.

Of the foregoing argument, as of all theoretical considerations, it may be said that the value lies in its providing a lead for further investigation and observation. This is something since it comes at a time when no progress is being made.

SUMMARY

Epilepsy is considered as one of the abiotrophies, or degenerations of the nervous system that depend on inherited predisposition. Among these are a number, for example Huntington's chorea and myoclonus epilepsy, that show a combination of mental deterioration and extrapyramidal motor disturbance. This combination suggests the possibility that the epileptic convulsion itself may be an extrapyramidal disturbance. Without considering the pathological process Krisch and Wimmer have arrived at the conclusion that such is the case. Myoclonus epilepsy presents a combination of an extrapyramidal disturbance, myoclonus, with seizures that suggest a common pathological process and localization for the two symptoms. The implication for epilepsy is obvious. If we accept that the specific factor in the causation of epilepsy is a degeneration in one of the extrapyramidal nuclei, we must concede as exciting factors of the individual fit any influences that heighten nervous tension at least in a certain way.

Bilateral Abducens Paralysis Associated with Paralysis of Convergence

J. PAUL DE RIVER, M.D.

San Francisco, California

The loss of the function of an organ is of twofold importance; primarily to the patient and secondarily to the physician. A clear understanding of the anatomy and physiology is a fundamental requisite when searching for the etiology. It is also essential that a knowledge of the anatomical distribution of the nerve elements supplying the given part be understood, together with the function of such nerves of supply.

Sight is undoubtedly the most valued of the five special senses. Thus, any disturbance of the visual acuity, whether directly due to a lesion in the eye or visual pathway, or indirectly resulting from motor paralysis of the extraocular muscles, becomes a matter of great concern, a handicap to the patient and a problem for the physician to solve. Granting this, it behooves us to acquaint ourselves thoroughly with the motor and sensory nerves supplying this organ, ever remembering the close relationship between the eye and the great coordinator, the brain.

While this subject deals with motor paralysis, it will not be amiss to remember that the eye is but an offshoot of the brain; the retina being an outgrowth of the rudimentary brain of the primary optic vesicle, and the optic nerves being parts of the lobes of the brain. If we think of the eye in these terms it will help us to understand why, in certain diseases of the brain and nervous system, the eye with its adnexa is so frequently affected. At times the symptoms appear very nearly in the course of some grave organic disease whose primary changes are manifested in a visual disturbance or loss of motor function, resulting from degenerative lesions or biochemical changes in the blood, as in syphilis which affects the delicate and highly specialized nerve tissue. They may also be due to direct mechanical interference with the function of the part, i. e., pressure due to neoplasms, etc.

It is a good deal of a shock to an apparently healthy individual suddenly to realize that his precious sense of sight has been reduced or completely lost, or that his field of vision is limited by paralysis of one or more ocular muscles. Often in the course of a hurried examination the busy doctor overlooks such conditions. Nor does he learn of his erroneous diagnosis until a more observing colleague goes over the patient. Were this the finale of the act it would be serious enough, but unfortunately it isn't. Consider the time the patient has lost seeking the cause of his trouble and the expense entailed. Also the doctor's unpleasant duty of informing the patient that his condition is beyond cure.

In considering the causes of the early symptoms of many grave diseases of the brain and central ner-

vous system which manifest themselves through the medium of the eye, let us remember what von Graefe said: "About one third of ocular paralysis is due to syphilis." Although I believe this to be a low estimate, considering the rapidity with which the disease has progressed, I shall leave it to the readers' judgment and return to the discussion of one or two of the most common conditions encountered early in syphilis.

Convergence paralysis is a condition very often overlooked, yet I believe it as positive a sign and as frequently encountered as the Argyll Robertson pupil which we associate with tabes and progressive paresis. That it is not more often found is because we do not test the power of convergence as thoroughly as we should. We therefore overlook a most valuable sign, which is often the earliest and only one of the disease.

I have come across convergence paralysis in innumerable cases. Some of them presented few subjective symptoms, and denied ever having a primary lesion. However the Wassermann test was positive. Let me add that I do not content myself with a blood Wassermann, for a number of my cases gave a negative blood Wassermann while the report on the spinal fluid was positive. For this reason I reiterate: "It is just as important to test the power of convergence as it is the pupillary reaction." If a patient shows a paresis or paralysis of convergence, provided his visual acuity is not reduced, I attribute it to syphilis until proved otherwise.

Authoritative textbooks tell us there are other causes of convergence paralysis, namely: multiple sclerosis and disseminated sclerosis accompanied by a form of nuclear palsy which may cause the loss of power of convergence without the loss of lateral movements. The sight of the lesion causing this disturbance is thought by many to be located in or near Deiter's nucleus in the medulla oblongata. Bernheimer believes the anatomical sight of the lesion is in the fibers connecting the nondecussating fasciculi of the two internal recti nuclei with each other, or connecting their fasciculi with the cortex. In Edinger's seventh edition of *Lectures on the Structure of the Nervous System,* his theory is that the centre of convergence may be formed by the large cell median nucleus of the oculomotor nerve, associated with the nerve cells for the rectus internus which lies on either side near the median nucleus, and that these groups may have a common centre of convergence. Many even doubt the existence of such a centre. However, my clinical experience, based on the number of cases encountered, leads me to believe that one does exist.

From a condition that is quite common let us turn our attention to one that is less so, and, when it does exist, may occur independently or be associated with a convergence paralysis. I now refer to paralysis of divergence. As to the location of the centre of divergence, Duane maintains that a paralysis of divergence may be explained by lesions near the two abducens nuclei. It has been further stated that the causes of divergence paralysis may be of basilar or nuclear origin, the diagnosis being largley based on the accessory symptoms. Bilateral paralysis of the sixth nerve have been noted in tabes (Landolt). Certain acoustic tumors at the level of the pontine angle of the cerebellum can produce the aforesaid condition; but as a rule other nerves are involved and we have the accompanying symptoms of vertigo, nystagmus, ataxia and other conditions, indicating disease of the cerebellum or labyrinth. This conditions has also been noted in syphilis, tumors of the posterior portion of the pons near the median line and aneurysms of the basilar artery.

In dealing with divergence paralysis let us consider the course of the abducen nerve which supplies the external rectus muscle. The nucleus of origin is the lowest of all the motor nuclei of the eye, and is situated behind the pons in front of the ementia teres in close proximity to the facial nerve. The root fibres of the sixth nerve do not cross with those of the opposite side. The fibres unite within a single bundle, pass forward and cross the medial longitudinal bundle, traverse the trapezium and appear at the base of the brain between the pyramids and the posterior border of the pons. It then courses forward and upward along the median extremity of the petrous portion of the temporal bone, over the apex of which it curves and enters the cavernous sinus. In the sinus it lies close to the internal carotid artery, following the ophthalmic division of the fifth nerve; penetrates the orbit at the inferior extremity of the superior orbital fissure, and enters the muscular cone (Landolt).

The diagnosis of convergence paralysis is based on the subjective and objective findings. The patient complains of double vision, increasing as the objects approach, and eye strain. The objective signs are crossed diplopia in the primary fields, remaining the same in all other fields. The near point of convergence is increased, with exotropia for near and possibly orthophoria for distance. Extraocular muscle movements may remain normal, revealing no individual muscle paralysis.

Divergence paralysis is usually a primary condition, characterized by diplopia, homonymous in type. It increases as the test object is moved distalward, and diminishes as it approaches the eyes until a near point is reached, when there is a single vision with orthophoria. The diplopia remains the same in all the fields of fixation. There is no individual muscle paralysis. This condition must be differentiated from bilateral abducens nerve paralysis. In the latter condition there is limitation of motion of both eyes; they cannot move outward beyond the midline.

The following case is of interest because of the mixed type and unusual character:

Case.—N.E.T., robust white male, aged thirty-two, laborer, married and had one child which was sickly; wife's health was good, no miscarriages and no still born children.

Past history was negative, except for syphilis in 1919. At that time patient said he was given a three months' course of treatment, including salvarsan and a course of mercury. Repeated Wassermanns had been negative, according to his statement.

The subjective symptoms were languor, headache and double vision.

Eye symptoms started about three months previously with double vision when looking at distant objects, and increased when he attempted to look to the left or right.

Examination July 16, 1926: Physical findings negative other than increased patella reflexes. Ophthalmic examination revealed: Vision 20/30 o.u. cor-

rected to 20/20 o:u. with a plus 75 cyl. and 90 axis. Fundi and media clear; pupils equal, and reacted to light and accommodation. No nystagmus or corneal sensibility was present. Convergence near point 200 cms. with crossed diplopia. Beyond this distance there was no diplopia in the primary field, but on looking to right or left there was homonymous diplopia. Eyes did not move in outward direction beyond the midline, thus revealing a complete bilateral paralysis of the external recti muscles. Spinal Wassermann was ordered, and reported positive.

This case should be classified as a mixed type, evidently due to syphilis. The sight of the lesion was probably nuclear.

SUMMARY

A routine examination of the eyes is important in all neurological cases. Changes in this organ frequently manifest themselves early in the course of the disease, and at times before any other signs or symptoms are present.

It is well to test not only the visual acuity, but to make a careful examination of the fundi and ocular muscle movements in the six cardinal positions. In this way various ocular muscle anomalies may be readily noted. Lastly, a careful perimetric examination is of untold value.

Cerebral Tumors and Psychoses

ALFRED GORDON, M.D.

Philadelphia

The special efforts in the field of anatomical and biological investigations contributed considerably to the solution of some psychiatric problems. As examples we may mention: the discovery of spirochetæ in paresis; the distinction of specific senile diseases from those dependent on arterial changes; the discovery of presenile mental states (Altzheimer's disease), the distinction of epilepsy, due to lues, to arteriosclerosis and to encephalitis, from essential epilepsy; the description of some forms of idiocy due to tuberous sclerosis; the discovery of amaurotic family idiocy; the discovery of congenital luetic diseases; the discovery of certain disturbances of development. Furthermore, we are making efforts to find morphological changes in dementia precox, in epilepsy, also changes of finer character in toxiinfectious processes, namely disturbances in the innermost relation of nerve cells and glia, which appear to form a living unity and react jointly to any irritation, to injury or to any other given disorder, and in which alterations take place according to the period of the disease. The brain is only a part of the ensemble, and its diseases are frequently not primary but secondary to invasion of other organs.

The development of clinical psychiatry commenced with the point of view that there is a relationship between mental and somatic diseases, between the psychical and the physical. The modern researches are continuously contributing to such a conception. While it is true that mental diseases are disorders of the brain, it does not always mean that in every case the brain changes must be of a morphological character, but there are reasons to believe that the psychic manifestations are due to or at least are brought out indirectly under the stimulating influence of the more or less fine changes in the brain. All sorts of cerebral alterations, gross, small or fine, may be accompanied by mental disturbances of all varieties, but the already accumulated and the still continuously accumulating evidence point to the conception that local brain changes of any degree or dimension do not act as a primary and unique etiological factor in production of mental disorders. They favor rather the idea that like any other factor, they play the rôle, although not negligible, of an exciting or a stimulating character and consequently they may be considered as an indirect etiological factor in the development of mental disorders. The problem therefore of a possible relationship between mental disorders and anatomical changes in the cerebral tissue is vast and far from being solved. The present study was undertaken with the object to attempt to answer some mooted questions of this difficult problem. It deals with gross organic lesions of the brain which during the patients' lives were associated with psychotic disturbances. It seeks to establish a relationship as a cause and effect or a corresponding parallelism between material diseases of the brain and profound disorders in the mental life manifested in the loss of power of composing and decomposing, of integrating and disintegrating images and thoughts by which mental life is characterized.

Eight cases with autopsies presented somatic symptoms and mental phenomena. The latter were most conspicuous and sometimes overshadowed the focal symptoms to such an extent that the diagnosis of psychoses was maintained for a long time to the exclusion of other possibilities. In the following reports many details of the physical symptoms will be omitted.

Case I.—Dural endothelioma (Mallory's arachnoid fibroblastoma containing a great quantity of fibrillar tissue between the cells) at the base of the brain immediately behind the frontal lobe and involving also the meningeal covering of the latter in the left hemisphere thus compressing the left orbital cortex.

Patient, K. O., female of forty, in whom there developed two years before death headache, dimness of vision in the left eye, also loss of smell on the same side. Ophthalmoscopic examination showed a great fullness of the retinal bloodvessels. There were no localized symptoms referable to the motor apparatus. Six months before she died there was noticed a gradually oncoming weakness of memory particularly for recent events: she would forget what happened only one hour before, what she ate at a previous meal, the days of the week. At times she would become confused so that she would not fully recognize her own people or her children. At times she would become exuberant and express pleasure upon the least attention of her nurse. At other times she would be capricious, impatient and restless. As a constant and continuous symptom there was an olfactory hallucination: she would smell the odor of gasoline in her room. It distressed her considerably as she would smell it even in her food, in the water she drank. Drinking would bring on an attack of vomiting which would be abundant. The odor of gasoline nauseated her. Pneumonia developed and the patient died.

Case II.—A large cystic mass in the left temporal lobe pressing upwards upon the entire left hemisphere, especially in a forward direction, compressing and disfiguring the frontal area and at the base displacing the bulbar region.

M. O'D., male, thirty-nine years of age, presented during a period of sixteen months the usual manifestations of increased intracranial tension: Vertigo, insomnia, headache, and during the first five months of his illness no changes in the ocular fundi could be seen. There were, however, changes in the visual fields, viz., concentric contraction more in the right than in the left eye. There was also considerable bilateral deafness. It was noticed that frequently the patient would become confused and disoriented with regard to space. During those periods, which, however, lasted two or three days, it was impossible for him to find his room in the house, or when he was out for a walk he could not locate the street and the house where he lived. When told to advance in a certain direction, he was unable to do it correctly. At that time the eyegrounds did not show any perceptible changes. He was able to appreciate objects shown. At times the confusional state would be so pronounced that a mild delirious state would appear and then he would have illusions of identity; he would not recognize his sister and would call her by a wrong name; his wife would appear to him as his mother although she was considerably younger than he. Gradually these mental manifestations became less and less frequent, but they never entirely disappeared. During the last two months the patient became childish and this mental puerility remained until his exit; he would laugh like his two small boys; he would handle and caress dolls and toys like them; his remarks about them and the language he used were those of his children.

Case III.—Glioma of the left hemisphere involving the supramarginal gyrus, angular gyrus, the posterior third of the first temporal convolutions compressing and encroaching upon the left frontal lobe.

E. C., male, presented all the general symptoms of intracranial hypertension, viz., bilateral optic neuritis, a history of vomiting in the early phase of the disease, persistent cephalalgia and insomnia. At various intervals there were also present generalized convulsive phenomena. Moreover, there was word blindness and deafness in the left ear. Information obtained showed that the patient passed at first through a period of great restlessness and agitation. At the time of my observations, which lasted six weeks, the following mental picture was present: there was considerable alternation of a joyful attitude and a depressive state. The first would occur when the headache subsided; he was then loquacious, would greet effusively every one who entered his room and at the same time there was a certain childishness in his behavior; he would laugh at trifles, at insignificant remarks; he would burst out laughing at his own expressions. After a brief period of this state he would become morose, would hardly respond to questions, would become angry without provocation. He would not ask for food. The alternating periods of exaltation and depression continued until the last two weeks, when several convulsive seizures occurred in rapid succession, after which profound depression dominated the scene until the patient's death. The alternating mental picture was so striking that a diagnosis of manic depressive psychosis was made by another physician who thereupon advised commitment.

Case IV.—Large cystic mass involving the ascending frontal, ascending parietal, a part of the temporal lobe also the posterior portion of the frontal lobe proper in the right hemisphere.

N. C., male, twenty-eight years old, was suffering from focal epilepsy with convulsions on the left side. The attacks occurred only occasionally. There was also severe headache and a double optic neuritis. There was apathy; disinterestedness was conspicuous even when the patient's headache was at its minimum. At the same time his judgment on most elementary subjects became defective, particularly with regard to propriety and conventional rules. He soon became profane in his language and comportment; he would masturbate and exhibit himself in the presence of his own family. He became irritable, quarrelsome, and on many occasions would attempt to attack. This total change of character and disposition, which formerly were most agreeable, remained unaltered until his death which took place in an attack of convulsions.

Case V.—Two cystic cavities in right frontal lobe.

N. D., aged fifty, presented a mild left hemiplegia, double optic neuritis, occasional attacks of convulsive seizures in the right arm and leg, occasional attacks of severe headache. The mental symptoms were euphoria with unusually clever repartees persisting until the end. This attitude was interrupted by a short period of a stuporous and confusional state following a convulsive attack; the duration of this state was unusually long, viz., seventeen days, and while under its influence there were hallucinatory episodes of several hours' duration and of an auditory character. The patient died subsequently in one of the convulsive attacks.

Case VI.—Cystic cavity with hemorrhage in the right prefrontal lobe.

A. C., male, forty-three years old, music teacher, gave a previous history of severe headache with a right hemiparesis. The mental manifestations predominated throughout the entire illness which lasted sixteen months. Euphoria of a pronounced character interrupted by phases of disorientation were the chief features. The latter manifestation occurred only at intervals, would last from seven to ten days, and had reference to space and time: the patient would frequently think he was in a strange house, that he was on the third floor: "he would consider himself living in the sixteenth century" and he feared the inquisition. This condition would subside gradually and then disappear. The patient reentered the former state of euphoria which was pronounced and associated with a certain degree of mental puerility; childishness in acting, feeling and thinking was in evidence and this continued until pneumonia developed from which he died in a short time.

Case VII.—Sarcoma between the frontal and temporal lobes in the left hemisphere.

D. K., thirty-nine years of age, presented a previous history of severe headache with double optic neuritis and one temporary attack of motor aphasia. During a period of eleven months before his death patient had frequent outbreaks of a maniacal character. Boisterous, speaking loudly of his accomplishments, of his great abilities, restless, impatient and at times aggressive he would frequently become distinctly delusive with persecutory tendencies. The delusions were of a fixed character, they were systematized and directed against certain personalities, and they were accompanied frequently by visual hallucinations. During the delusive periods the intensity of the ideas, the great aggressiveness accompanied by actual threats were so striking that he was considered by some psychiatrists as suffering from typical paranoia. However, prolonged observation revealed the fact that these were only temporary phenomena, although repeated, between which depression would set in and there would be no trace of these manifestations. At one time the possibility of paresis was considered in view of the presence of small pupils, increased reflexes with an occasional extensor plantar reflex on the right side and the thick and heavy pronunciation of words. Patient contracted typhoid fever in the course of which he died.

Case VIII.—A cystic tumor with hemorrhage in the right frontal lobe.

G. S., male, forty-five years of age, presented for a long time paroxysms of severe headache with vomiting, also a mild left hemiplegia with slight attacks of subjective sensory phenomena on the same side, very brief in duration and without loss of consciousness. There was also optic neuritis on one side.

The mental phenomena consisted chiefly of alternating brief periods of exaltation and depression. In the first there was a very marked euphoria, in the second profound apathy during which the patient would be almost totally mute, would only occasionally utter indistinct words. In the intervals the patient showed the attitude and behavior of a child; would laugh at the least remark, would speak of small matters, of facts which occurred in his childhood, describing them and laying emphasis on occurrences which could interest only a child. Towards the end of his life his memory became markedly defective and he frequently would pass through phases of confusion with disorientation in space. The patient died suddenly.

SUMMARY OF THE MENTAL PHENOMENA IN THE EIGHT CASES

1. Euphoria was present in five cases. It figured as a maniacal manifestation in those cases which resembled the syndrome of the manic depressive psychosis. 2. Depression was present in five cases. Like the euphoria it was present in those cases which resembled manic depressive psychoses. 3. Alternating phases of depression and exaltation were present in two cases. 4. Puerilism was present in four cases. 5. Disorientation with confusion was observed in five out of eight cases. The largest majority of the cases therefore presented the manifestations of euphoria and disorientation accompanying confusion. Puerilism was next in frequency. In only one case the paranoid symptom group was in evidence.

Analysis of the individual manifestations presents the following peculiarities. The phases of exaltation and depression strongly resemble those of the manic depressive psychosis but a closer observation showed that in the first phase there was invariably a state of mental puerilism which is ordinarily not observed in the classical psychosis. The puerilism was evident in speech, behavior and in the relation to everyone who came in contact with the patient. The exaltation was associated with a sarcastic state of mind; the ironical remarks did not lack in intelligence; on the contrary it was at times very subtle; it did not possess the pretentious, ridiculous and absurd character which is observed in cases of paresis, neither did it present the indefatigable picture of the maniacal attitude. The depressive phase was not that in which indifference, apathy and abandon figure so prominently in the classical psychosis. In the present series of cases the patients were morose, would hardly respond to questions and would show outbursts of extreme anger even without provocation. Sometimes each of the phases would be accompanied by a certain amount of confusion which again is not observed in the classical psychosis. The socalled depressive state which at first was only intermittent or occasional gradually became more persistent probably because of the progressive increase of cerebral hypertension when the mental and effective activities became gradually extinguished and the automatic activity alone remained: one witnessed a gradual loss of interest, a gradual slowing up of judgment and of the power of perception, a genuine inertia which of course ran parallel with the motor inertia. The maniacal phase was sometimes accompanied by a distinct impairment of the mnemonic faculties which again is not the case in the typical manic depressive psychosis. It is singular to observe that in some cases the impairment of memory was not continuous through the largest period of the illness: at times events would be recalled with great facility, at others there would be almost total amnesia for old events, and still at others only for recent events, and in some cases for both recent and old occurrences. In the latter case the clinical picture resembled dementia. In such cases paretic dementia was not rarely thought of especially when

there was an association of tremor, changes in fundi oculorum and a history of brief attacks of convulsive seizures. Two of the patients were musicians. When the memory would become affected there would be also an involvement of the musical faculty. The periods of memory involvement strikingly affected all sorts of events and in attempts to recall those of youth or of childhood the patients exhibited a hard and painful struggle with themselves, omitting important details, talking very slowly, and deliberately. At no time, however, was there any tendency to confabulation such as is observed in Korsakoff's psychosis. There is another distinctive feature worth mentioning: The alternating phases of exuberance and depression were not constant; they would appear at different times in the course of the disease and for very brief periods, and in the intervals between the latter other mental manifestations would be in evidence.

The puerilism mentioned above which was found frequently in my series was rendered striking by the infantile character of the patients' replies, by the intonation of the voice, by the mimicry, by the childish interest in things childish, by the impatience and obstinacy typical of children in their motives and desires. Puerilism was associated with the exuberant phase and in some cases it was an independent phenomenon. It was not a manifestation of confabulation of the Korsakoff type nor of a delusional state nor of dementia. Besides, it would disappear completely and reappear repeatedly. It was only towards the termination of the disease when the intracranial hypertension reached its maximum, when cerebral inhibition was more and more profound and judgment and perception showed progressive increase of inhibition, that the puerilism, when present, would form one of the phenomena of a demented state.

Another frequent manifestation was disorientation. The latter affected space and time. It is to be observed that this phenomenon was not constant in the course of the original disease; it would be associated mostly with a confusional state which by itself was only temporary although it occurred repeatedly. In the intervals careful investigations were made with regard to the nature of the disorientation. All elements normally connected with the appreciation of space were examined as far as it was possible. Vision, ocular movements, and fixation, superficial and deep sensibilities, the condition of the labyrinth, the auditory apparatus, otherwise speaking, all factors which participate in kinesthetic coordination and orientation in normal life—were all found intact.

Evidently the disorder in the orientation was due to the patient's failure to integrate automatically all kinesthetic perceptions, and in view of the fact that the disorientation was closely associated with the confusional phases and was absent in the intervals, it is to be presumed that the inability to integrate and the resultant disorder in the dynamic conception of bodily displacement was of a purely psychic character, a fact which is so frequently observed in psychoses.

The foregoing analysis of individual manifestations shows that each and all while resembling those usually encountered in the course of psychoses, nevertheless are wanting in the typical features of the latter. Moreover, the most striking characteristics are found in the fact that in all the cases the individual psychotic phenomena, although repeated, were only temporary and transient, in the intervals of which the patients were lucid. We observed it not only in the cases cited, but also in Case VII in which the patient presented a paranoid syndrome with all its typical symptoms.

Case IV resembled for many months cases of dementia precox. Manic depressive psychosis, primary confusional insanity, paresis, mental deficiency were all affections simulated in the cases under discussion. All the eight cases presented this peculiarity that at any given time the mental phenomena were so predominant that they led to errors of diagnoses. They were considered as examples of pure psychoses until the time when the physical characteristics became more and more conspicuous.

Let us now attempt to trace, if possible, a relationship between the psychic manifestations and the destructive states of certain areas of the cerebrum. In Case I temporary but mild confusional states with involvement of memory, temporary exuberance, capriciousness and olfactory hallucinatory phenomena were all associated with an endothelioma at the base of the frontal lobe. In Case II marked confusional states with disorientation and puerilism were associated with a large cyst in the temporal lobe pressing forward against the frontal lobe. In Case III manic depressive manifestations with puerilism were associated with a large glioma which destroyed the angular gyrus and temporal lobe encroaching upon and compressing the frontal area. In Case IV, depression and modification of character and of behavior were associated with a large cystic mass affecting the two ascending convolutions, the temporal and posterior portion of the frontal. In Case V manic depressive manifestations with a pronounced euphoric phase, with temporary confusion and disorientation were associated with two cystic cavities in the frontal lobe. In Case VI manic depressive manifestations with pronounced euphoric phases, also temporary confusional states with disorientation and puerility were associated with a hemorrhagic cyst in the frontal area. In Case VII outbreaks of a condition with temporary paranoid states were associated with a sarcoma lying between the frontal and temporal lobes. In Case VIII manic depressive manifestations with a pronounced euphoric phase, puerility, also confusional periods with disorientation were associated with a large hemorrhagic cyst in the frontal lobe.

It seems, therefore, that the frontal and temporal lobes were particularly involved when manic depressive manifestations were present. When the frontal lobe alone was frankly and grossly involved the maniacal phase with euphoric tendencies was especially conspicuous. Confusion with accompanying disorientation was present when the frontal lobe was only distantly pressed upon. Psychic puerility was also present mostly in the gross and direct involvement of the frontal lobe. The same may be said of the disturbances of memory. The one delusional state (paranoid) was also present in the case of a gross involvement of the frontal lobe, in which the sarcomatous tumor inserted between the temporal and frontal lobes compressed considerably more the latter than the first. In all cases the frontal lobe was more or less invaded.

As to the mental manifestations themselves, we

find in the present series of eight cases a great variety simulating more or less strongly the classical psychoses. In August, 1914, I published a case (1) of sarcoma of the basal ganglia and the patient during life presented an almost typical picture of paresis. This neoplasm was of such a size as to produce considerable pressure on the anterior portion of the brain thus involving the frontal lobe. The symptom group of senile dementia is not rarely met with in cerebral tumors. Constantini has recently published such a case; a patient of seventy-two presented all the typical symptoms and at autopsy a tumor was found in the left prefrontal lobe. The same author (2) in recording other cases lays special emphasis on the occurrence of mental disorders in a simultaneous involvement of the frontal and temporal areas of the brain. Shuster (3) after an extensive study of 775 cases is inclined to believe in a certain relationship between the type of mental disorder and the seat of the neoplasm. The cases published here seem to favor such a view. It appears that the organic invasion of the cerebral substance which contains the motor and sensory speech centres is particularly apt to disturb seriously the mental operations. The study of all cases indicates also the possibility of graver mental disturbances such as maniacal, euphoric or else depressive states, psychic puerilism, perversion of mnemonic faculties, delusional conceptions, phenomena suggesting dementia precox—all associated with gross and direct lesions of the frontal lobe. On the other hand less profound mental manifestations are met with in cerebral lesions (tumors, etc.) of other areas but sufficiently extensive to invade to a lesser degree the frontal area.

So far the present study and that of other writers with positive findings may claim a certain relationship between the destructive lesions of the brain substance and certain mental phenomena resembling those encountered in psychoses, also between the character of the psychic disorder and the localization of the organic lesion.

When one looks for a pathogenetic explanation, one may think of absorption of toxic elements originating in the tumor by the venous and lymphatic circulation; one may also consider a secondary infectious process which develops around the tumor and produces an inflammation in the meninges, in the ventricles. The analogy between the clinical piciture of uremic encephalopathy and that of cerebral neoplasm is striking.

Besides extraneural toxemias other factors have been considered in all such cases. In a recent contribution J. F. Bateman (4) presents the material of 666 brains from insane individuals in which closures of the foramina of Luschka were 11.6 per cent. In all such brains there were found atrophies, lesions, softening and general loss of brain substance. By obstruction of foramina which interferes with the normal flow of cerebrospinal fluid waste products are allowed to accumulate. This circumstance together with insufficient nutrition of brain cells from a deficient blood supply in tumors produce progressive degenerative changes and a loss of mental faculties.

Autointoxication, secondary infection, irritation from intracranial hypertension may explain the presence of many mental manifestations, but do not interpret the development of the psychotic phenomena in the course of brain tumors such as we find in genuine psychoses. The fact that there are cases of cerebral tumors without psychotic disturbances, the fact that in the positive cases those disturbances were transient and temporary and that a close analysis of the mental phenomena showed some differences from those encountered in genuine psychoses—all those circumstances do not permit to accept a close or an intimate relationship. Nevertheless one cannot abandon the possibility of some relationship as seen in the present series of cases as well as in the records of other observers. It is true that the clinical pictures of psychoses in cerebral tumors are not complete and their characteristic features are not mathematically identical with those of the classical psychoses, nevertheless the resemblance between the two is very strong and generally speaking the individual phases are correctly reproduced.

In reviewing the present series of cases as well as those reported by many others there is an inclination for incriminating the frontal lobes. It was mentioned above that in direct and gross involvement of these portions of the cerebrum the mental phenomena simulating psychoses were more conspicuous and more profound than in cases where the frontal area was involved indirectly, such as in pressure from a distance. Forms of high grade dementia are reported by Curti (5) in neoplasms of the anterior fossæ. Similar cases are reported by Richter (6), by Gans (7), by Marie et Benoist (8), by Arvedo (9). Symptoms similar to those of paresis were observed in tumors of the frontal lobes by Bernhardt and Borchardt (10), by Sullivan (11), by Van Gehuchten (12), by Witney (13), by Rosenheck (14), by A. Gordon (15).

The corpus callosum by virtue of the ample connections which it establishes between both frontal lobes, could be considered as an integral part of the frontal brain, so that lesions of the former cause about the same symptoms as those of the latter. The statistics of H. di Gaspero (16) show that psychic disturbances occur more frequently in tumors of corpus callosum than in any other part of the brain; the temporal, parietal, and occipital tumors follow in order. The World War has supplied some material in this direction; persons with frontal brain injuries showed greater mental defect than those with lesions in other parts of the cerebrum. Bayerthal (17) gives a good account of such occurrences. If we add the experimental observations on animals and those of comparative anatomy, it becomes evident that the frontal brain possesses a prevailing psychic significance (See also the article of J. Donath). All such studies while they do not settle definitely the question whether the frontal lobes form a special centre for psychic functions, nevertheless they suggest the possibility of their possessing the power to coordinate the psychic functions more than any other portion of the cerebrum.

CONCLUSION

The present study does not permit me to draw strictly definite conclusions, but it appears highly suggestive in a certain sense of relationship or of interdependence between the psychotic manifestations and the destructive lesions within the cerebrum associated with or caused by neoplasms, more pronounced when the frontal brain is invaded. On the other hand in view of the fact that some tumors of

the brain are not accompanied by psychotic disturbances, one is justified in assuming that this relationship or interdependence is not absolute, and could therefore be considered only as a secondary etiological or pathogenetic element. A further analysis of this problem leads to further conclusions, namely that the fundamental disorder lies originally in psychogenic disturbances of the individual who under the influence of a morbid character, organic or functional, somatic or psychic, is inevitably prepared or potentially ready to break down and present at any time a picture of psychotic phenomena. The destruction of cerebral tissue in tumors and the accompanying intracranial tension which leads to the circulatory changes and the consequent nutritional disturbances of the cortical cells, the possible secondary inflammatory changes in the meninges, the possible accumulation of waste products within the cerebrum, finally, and perhaps the most important, functional changes in the great centres, especially in the frontal brain—all these factors conjointly or individually very probably play a secondary rôle, or are but exciting causes in the development of psychoses in the course of cerebral lesions, notably in cases of neoplasms. The variations in the clinical pictures, disappearance and reappearance of individual phases, or their substitution by different psychic phenomena—all of which render the clinical course irregular and incomplete and thus show a striking difference in the course of the diseases between psychoses associated with cerebral tumors and the classical psychoses—are still further in favor of the above view, namely they demonstrate the fact that the underlying psychogenic morbidity is constantly being disturbed by progressive cellular, arterial, meningeal and metabolic alterations which are bound to take place in the course of an organic disease of an inevitably progressive course. In the latter seems to me lies the strongest proof of the above pathogenetic view. Psychogenic disturbances are fundamental; basic brain lesions even of a gross character are only contributory in the development of psychoses.

Encephalitis: Atypical Modes of Onset and Clinical Manifestations

J. ALLEN JACKSON, M.D.
and HORACE V. PIKE, M.D., Sc.D.
Danville, Pa.

The continued and increasing number of cases that are presenting themselves with the residuals of encephalitis is a matter that is assuming larger proportions and at the present time bids fair to become a question of serious moment, not only from a medical but likewise from a sociological aspect, for many of these patients in addition to the purely physical handicap necessitated by this condition and its consequent economic inefficiency, also present definite mental disturbances that result in conduct disorders which render them distinctly antisocial and preclude an adequate environmental adaptation. At the present time the wards in the neurological divisions of general hospitals in the larger cities are filled with these patients, state hospitals for mental diseases are admitting an increasing number with definite psychoses and in some states the setting aside of special wards and the establishment of specific types of occupational therapy with a view of providing vocational training, especially for those under sixteen years of age, who are no longer able to continue their education in the public schools with profit to themselves and any degree of comfort to others, is being seriously contemplated.

Perhaps one of the most serious aspects of this problem is the difficulty of its early recognition and the multiform clinical manifestations which the disease presents, and it is with a view of being of service to the family physician, who in the natural course of events is the man who sees and treats these patients through the prodromal and acute periods of the disease, that the following observations made in connection with patients studied at the Danville State Hospital, both in the wards of the hospital and at its eight mental clinics, are herewith presented:

Apparently this disease is uninfluenced by age, sex, physical or environmental conditions. The patients studied have come from all walks of life, male and female patients have had a fairly equal representation, the extremes of life as well as puberty, adolescence and midadulthood have contributed their quota and the physically fit have succumbed with the weaklings.

Furthermore, it presents no well defined clinical course, its subjective symptoms vary with each individual case, and neurological signs are frequently absent or if present often indefinite and frequently misleading.

Likewise the end results cannot be predicted with any degree of certainty and patients who pass successfully through the acute period of the disease may promptly reveal marked disturbances of mental or physical functioning or apparent complete recovery may be followed by an insidious development of residual symptoms that may not be recognized until after a period of many months has passed, and these later manifestations may be of either a neurological or a psychic nature.

Not only do we find a great variety of clinical manifestations during the acute period of an attack and multiform sequelæ, but the mode of onset of the disease apparently follows no well defined course and may so simulate other conditions as to render diagnosis extremely difficult and often impossible, as may be seen from the following citations of atypical cases.

Case I.—A. J., female, aged eight years. The hereditary factors were negative. Normal birth and development both mental and physical until six and one half years of age, when she suffered a nocturnal convulsion of epileptiform character and which was attributed to gastrointestinal disturbances. Three days later a second convulsion occurred lasting for one hour and which was treated with hot baths and sedatives. During the succeeding four days she appeared quite normal save for a general irritability, anorexia and insomnia. This was followed by a series of ten convulsions occurring within twenty-four hours and the following day a right internal strabismus was observed. Throughout this period there was no elevation of temperature and between convulsions the child was up and about and out of doors, and the condition was diagnosed as epilepsy and treated as such. Subsequent history shows an arrest of mental development with consequent inability to learn in school, the appearance within three months of tremors of hands, pain in both upper and lower extremities and defect of speech. The condition has gradually progressed until at the present time, one and a half years after initial convulsion, all the neurological evidences of Parkinson's syndrome are well developed and psychometric measurements record a mental age of six years and seven months. There have been no further convulsions and blood and spinal fluid Wassermann are negative, as is the blood Wassermann of both parents.

Case II.—L. C., female, aged fifty years, married. First complaint of languor and chilliness, followed in forty-eight hours with aching, tenderness and swelling in the right parotid region which promptly extended to the opposite side. Temperature varied from 100° to 102° and within five days the clinical picture was one of mumps, which ran apparently the usual course and at the end of ten days all local symptoms had subsided. The temperature, however, did not decline and the patient became restless, mentally confused, delirious and finally passed into a condition of somnolence followed by stupor. Coincident with the mental symptoms focal manifestations of cranial nerve involvement occurred including ptosis, partial ophthalmoplegia externa, inequality and irregularity of pupils, left facial palsy and dysphagia. General muscular rigidity was increased, fibrillary tremors of the abdominal and thoracic muscles were present, deep reflexes were diminished and vesical and rectal incontinence were marked. All symptoms referable to irritation of the meninges were absent. Blood Wassermann negative. Spinal fluid negative safe for a slight lymphocytosis. At the end of three months patient began to improve and at the end of six months had completely recovered and at the present time, two and one half years later, shows no residuals of the disease.

Case III.—H. M., male, aged twenty-two years, single, clerk. Habits temperate, always physically well with exception of measles and diphtheria during early childhood, was awakened at night with nausea, vomiting, general abdominal pain which after twelve hours became localized in right iliac region and was accompanied by muscular rigidity and tenderness over the lower right abdominal quadrant. A diagnosis of appendicitis was made and surgical operation advised but refused by the patient who was thereafter treated symptomatically. Forty-eight hours later patient suffered an apparent collapse which passed into a condition of somnolence, stupor, and finally semicoma which extended over a period of six weeks after which he gradually convalesced and was able to get about and out of doors. He failed, however, to regain his former strength and at this time a slight ptosis and external strabismus of right eye were first observed. Six months later the syndrome of multiple sclerosis was definitely established in which horizontal nystagmus, dysarthria, intention tremors and incoordination of upper extremities, spasticity of lower extremities, increase of deep reflexes, positive Babinski sign and emotional instability were prominent. Blood and spinal fluid Wassermann negative.

Case IV.—L. B., male, aged thirty-one years, married, miner, habits temperate. Four years ago patient suffered an acute illness which confined him to bed for a period of six weeks and the condition was diagnosed and treated as typhoid fever. During the third and fourth week of the disease he manifested a maniacal delirium alternating with a condition of stupor. No neurological signs of organic brain or cord lesion were observed and patient made an uneventful convalescence. He returned to his work but appeared mentally dull and complained of pain and weakness of the lower extremities. Within two months he exhibited a marked change in disposition, displayed episodes of irritability and impulsiveness resembling psychic epileptic equivalents. He was forced to abandon his work and remained at home becoming emotionally depressed and at times hallucinated. The face became flushed, saliva began to escape from right side of mouth, tremors of the right hand appeared and progressively extended to the arm, head, left hand and arm and finally lower extremities accompanied by stiffness, rigidity and disturbance of equilibrum. Two years after the supposed typhoid fever all the signs of paralysis agitans were present and at the present time patient is practically bedridden and helpless.

Case V.—A. G., female, aged thirty-two years, married. Has given birth to two children. Has had no miscarriages and always been physically well. The youngest child is two years of age and at its birth during which labor was prolonged over a period of three days she was attended by a midwife. Five days after delivery there developed a general septicemia

from which she apparently recovered after several weeks. A few months later she experienced difficulty in walking, tremors appeared in both upper extremities, gradually she became mentally dull, emotionally depressed, at times confused to the extent that she would wander from home. Auditory hallucinations became prominent and an attempt at suicide led to her commitment to the hospital, where examination revealed a well advanced condition of paralysis agitans.

Case VI.—E. K., male, aged fourteen years, schoolboy, heredity good. Patient alert, good student and physically well save for frequent attacks of tonsillitis. On advice of physicians, tonsillectomy was performed. One week subsequent to operation and while throat was still unhealed patient complained of diplopia, headache and vertigo, temperature rose to 102° and forty-eight hours later a severe convulsion was followed by ptosis of right eyelid, nystagmoid movements and paralysis of right side of face. There was no stupor or delirium, temperature gradually declined and at the end of six weeks paralysis had practically disappeared. He returned to school but was unable to make further progress, marked conduct disorders developed and his delinquent tendencies led to his exclusion from the public schools and a year later to commitment to a state institution.

CONCLUSIONS

1. The organism of encephalitis may reach the central nervous system through many and varied channels.
2. Encephalitis in its mode of onset may simulate various other conditions to the extent of completely masking the disease.
3. Neurological signs may be completely absent or so slight as to escape detection throughout the acute period of the disease and only by its sequelæ be finally recognized.
4. All acute, general infectious diseases should be carefully studied from the neurological viewpoint with the possibility of encephalitis continually in mind.

The Serology of General Paresis in the Malaria Treated Cases

ARMANDO FERRARO, M.D.
and THEODORE C. C. FONG, M.D.
St. Elizabeth's Hospital, Washington, D. C.

The new era opened to the treatment of general paresis by the Wagner von Jauregg malaria treatment has already permitted M. Nonne (1), who for the past thirty-five years has been interested in the treatment of general paresis, to affirm that "the axiom of the incurability of general paresis can be now considered as untenable." What Nonne said in regard to the curability of paresis might also be said of the serology. Cases were known in which the serology, following intense specific treatment, showed evident improvement or even eventually recovery, but such cases, especially those reaching the degree of serological recovery, were rare. No later than 1920 Haguenau (2) in France who extensively studied the humoral syndrome of general paresis could still speak of the irreversibility of the serology by any kind of treatment; he considered this irreversibility as the feature differentiating paresis from other forms of syphilis of the nervous system.

In 1922 Rene Targowla (3) almost arrived at the same conclusion although he was less dogmatic as to the possibility of a certain reversibility especially in spontaneous remission periods, and in cases of atypical paresis. And very recently at a monthly meeting of the Neurological Society of Philadelphia Dr. Strecker asked if there were cases of general paresis on record with a negative serology.

The really great modification in our old conceptions concerning the serology of general paresis has grown up with the now widespread practice of malaria inoculation. The influence of such treatment on the serology has been hitherto neglected presumably because of the short time that malaria inoculation has been in use. As a matter of fact, Wagner von Jauregg (4) himself not later than 1922 expressed the opinion that "the malarial treatment has only a negligible influence upon the serum and fluid reactions and only in a few cases could there be established an influence worth mentioning on these reactions."

With the extension of the new method of treatment, observations on the serological reactions grew in importance and fixed the special attention of some investigators. However, curiously enough, from the same clinic as that of Wagner von Jauregg, Gerstmann (5) issued a paper in 1922 in which the serological modifications in a first series of 116 cases were reported. Gerstmann found that in cases with complete remissions there was an improvement of the Wassermann reaction of the blood, in 25.8 per cent. of the cases. The Wassermann of the spinal fluid was improved in 48.4 per cent. of the cases, the lymphocytosis in 87.1 per cent., the globulin in 46.6 per cent., and the albumin content in 77.4 per cent. In cases with partial remissions there was an improvement of the blood Wassermann in forty per cent. while the spinal reactions were improved as indicated by the following percentages: Wassermann 43.9 per cent., lymphocytosis 93.6 per cent., globulin 59.5 per cent., albumin 75 per cent. In some of the cases the Wassermann reaction became negative both in the serum and the spinal fluid in the following proportions. Cases with incomplete remissions: negative blood Wassermann 6.45 per cent.; negative spinal fluid Wassermann 12.9 per cent. Cases with complete remissions: negative blood Wassermann 13.3 per cent.; negative spinal fluid Wassermann 13.3 per cent.

The following year Weygandt (6) referring to some of the previous results obtained in his clinic in

Hamburg which were worked up by Kaltenbach, mentions the fact that of twenty-seven cases treated with malaria twenty showed an evident reduction of the three most important fluid reactions. Some favorable results were reported by Kaltenbach and Kirschbaum (7) who found an evident improvement of the cerebrospinal fluid following the above mentioned treatment. Ilse Graf (8) of Leipzig mentions an improvement in the serology, especially in the pleocytosis as well as in the Wassermann reaction which in one instance became negative in the cerebrospinal fluid.

However, contradictory results were reported by McAllister (9) who expressed himself in the following way: "At the moment the results on the serology are again being investigated, and so far as this has been done, Wagner von Jauregg's conclusion that the conditions of the blood serum and cerebrospinal fluid are not noticeably altered by the malaria infection, has been confirmed." It must be pointed out, however, that from the time of the malaria inoculation to the time of the publication of his article only seven months had elapsed.

According to Nonne, the pleocytosis is the element most influenced, while the globulin content improves and in some instances reaches negativity. The same favorable influence on the cytology, as well as on the albumen and protein content, was found by Peter and Reese (10). Besides, they found occasional improvement and even negativity in the cerebrospinal Wassermann.

In 1924, J. Purves Stewart (11) reported that in no instance was he able to find in the literature cases treated by malaria in which the cerebrospinal fluid returned to normal. On the contrary, he says, the characteristic pleocytosis and positive Wassermann reaction are observed to persist practically unchanged, despite the improvement in the clinical symptoms. We cannot quite agree with this statement as we have already mentioned the serological results reported by some authors as regards the pleocytosis as well as the Wassermann reaction showing a gradual tendency to return to normal. Positive results in the sense of serological improvements are also reported by Kirby and Bunker (12), and Grant and Silverston (13). The latter in a series of forty treated cases found that in every case there was some alteration following treatment, either in the fluid or the serum or in both. The earliest signs of improvement were manifested by a diminished lymphocytosis and lowered globulin content of the cerebrospinal fluid and by a reduction in the intensity of the blood Wassermann reaction. The Wassermann reaction of the cerebrospinal fluid and the colloidal gold were favorably influenced during a somewhat later period of treatment. Negative Wassermann reactions were obtained in the cerebrospinal fluid and in the blood in fifteen per cent. and 7.5 per cent. of the respective series. In two cases or five per cent. the liquor and Wassermann reactions were concurrently negative.

In a later article, Weygandt (14) states that the pleocytosis rapidly improves, and also very often the globulin content, and that the Wassermann reaction in both the serum and cerebrospinal fluid could become negative following treatment. Mingazzini, however, although agreeing as to the improvement in the lymphocytosis and in the albumin and globulin content, could not confirm the improvement of the Wassermann reaction of the cerebrospinal fluid. Sagel (15) and Bering (16) reported cases showing a very great improvement, and the latter author had cases showing complete serological recovery. Such a recovery was found in two cases by Charlotte Jacob (17) and in one case by Runge (18). Kirby (19) also reports a case with negative Wassermann reaction of the cerebrospinal fluid following the malaria treatment, while seventy-five per cent. of the treated cases were serologically improved. Eldridge (20) *et al* of Saint Elizabeth's Hospital in their article briefly reported serological improvement following malarial inoculation.

N. D. C. Lewis (21) reporting the earlier results of the first series of the malaria treated cases at Saint Elizabeth's Hospital also found that seventy-five per cent. of the treated cases showed serological improvement, and in one case he was able to get a negative Wassermann on the spinal fluid. In the discussion that followed the reading of his paper, Lewis added: "When I say serology became negative I mean that the Wassermann and the other reactions in the blood and spinal fluid became inactive or perhaps one might in some instances term the reactions very atypical. There are some changes still demonstrable in the spinal fluid which I presume indicate the patient will some time die of general paresis, but I think, as has been suggested, we have something here worth further experimentation to see what will happen."

According to the data of U. Fleck (22), the percentage of serological improvements following the malaria treatment is given as 30.8 per cent. for the blood Wassermann and 57.2 per cent. for the cerebrospinal fluid Wassermann. The data of B. Kihn (23) are, however, much less optimistic as the author mentions a consistent improvement in only ten per cent. of the cases and in no case did he see a complete negative cerebrospinal fluid. A. Wizel and L. Prussak (24) referring to the results of the serological changes, in the eleven improved cases of their series, mention that the pleocytosis disappeared entirely in three cases and diminished very greatly in three others. The Nonne and Apelt reaction (phase 1) became negative in four cases. The Wassermann reaction improved in five cases and became negative in four. The Wassermann reaction of the cerebrospinal fluid improved very much in four cases and slightly in another.

Bunker and Kirby (25) consider positive spinal fluid findings tend to become more or less slowly modified in the course of six months to a year or more subsequent to the treatment; that the cell count is the most quickly and easily affected and the Wassermann reaction is the most resistant while the colloidal gold curve becomes very slowly but eventually modified in the majority of instances and the globulin, although quickly reduced, as a rule becomes negative very slowly and only in a certain proportion of cases. The Wassermann reaction in the spinal fluid must be considered the most refractory feature of the total picture in the sense that although it undergoes some reduction more or less immediately, it seldom becomes completely negative. Their most usual experience has been that even at the end of a year or longer the reaction is still present (from two plus to four plus) in one c. c. of spinal fluid though negative in 0.5 c. c.

However, in their series of fifty-three cases, the Wassermann reaction of the cerebrospinal fluid was found negative twice out of twenty-nine following three months of the treatment, three times out of nineteen after six months and once out of five after one year.

Solomon and Berk (26), although finding serological modifications in malaria treated cases, cannot say much about the effect of malaria on the serology because they have been following the malaria treatment by tryparsamide, so that the changes, according to their views, may have been caused by agents other than the malaria. As a result of his experience, M. Graham (27) found that serologically the results were not very obvious, but he admits that a further examination is advisable in order to determine more accurately the value of the treatment.

At the seventeenth meeting of the Italian Society of Psychiatry, Pisani (28) reported that in the great majority of the cases following the malaria treatment the single components of the cerebrospinal fluid show a tendency to improve even in the absence of a corresponding clinical improvement and even in cases showing eventually a tendency towards aggravation. In cases showing clinical improvement the fluid has a definite tendency to recover and sometimes may become entirely normal. In some of the cases unchanged clinically, as well as in those which became worse, a trend is noticed towards regression and the fluid reactions may revert to their previous pathological condition. The pleocytosis diminishes at the outset while the decrease in globulin follows a slower course than the colloidal reactions. The Wassermann reaction persists for a long time and, as a rule, improvement only is noticeable. In a few cases, however, in the years following the malaria inoculation the Wassermann may become negative.

Recently Gerstmann (5), in his detailed work on the malaria treatment of general paresis, dedicated a special chapter to the serological modification confirming what he already mentioned in his previous paper that, in the majority of the cases, there is a rapid improvement of the inflammatory reactions (lymphocytosis, albuminosis) while the Wassermann reaction and the globulin content do not improve for several months or even several years after the malaria treatment.

H. Claude and Targowla (30) nine months after the malaria inoculation of their patients find that the serological changes are of little importance and sometimes no changes are noticed. However, the lymphocytosis and the hyperalbuminosis are often improved while the colloidal reactions are very little modified and the Wassermann becomes partially positive. The same resistance of the Wassermann and colloidal reactions are reported by W. York (31). From the data collected by E. Nicolle and P. Steel (32), a serological improvement is seen in fifty per cent. of the treated cases if a serological examination is made at a sufficiently long interval after the malaria treatment.

Finally pessimistic results are reported by Bouman (33) and by Grimme (34), who, out of thirty-six cases treated, found only one with complete recovery of the blood and spinal fluid, while in the remaining cases they noticed no changes.

The serological modifications in the cases treated by malaria have also been studied by some of the investigators from the standpoint of the relationships between the serological and clinical improvement. Gerstmann (35) was among the first to establish a lack of parallelism between these two sides of the pathological picture, but recently he appears somewhat less affirmative as he establishes a division between the early and the later changes following malaria treatment. This author finds that when a long period of time has elapsed after the malaria treatment the discordance between the clinical and serological changes, so striking in the early stages, gradually disappears.

Weygandt believes that a certain parallelism does exist between the serological and clinical changes although they are not definite, while, on the other hand, a lack of parallelism is reported by Templeton (36), Kirshbaum and Kaltenbach (7): *"Zwischen Veränderungen im klinischen Bild und den Veränderungen der Reaktionen in Liquor kein Parallelismus besteht."* The same results are reported by Reese and Peter (10) and McBride (37). In the same direction, Kirby and Bunker (25) quote some of their cases where they found complete reduction of the Wassermann reaction and flattening of the colloidal gold curve without any corresponding mental improvement. On the other hand, cases clinically improved while the serology still showed definite changes are reported by Sagel (15), Bering (16), and Fleck (22). The lack of parallelism is also confirmed by N. D. C. Lewis (21) and in a later article by Kirby and Bunker, as well as by W. York (31).

Mingazzini (38) and his pupil Pisani (28) are inclined to accept a certain parallelism, at least in a general way, as they found that the serology becomes worse in the cases showing an unfavorable course.

The serological results following malaria treatment have also been investigated by some authors from the standpoint of their prognostic value. Wagner von Jauregg (4) himself denied such a value while Potzl and O. Fischer have attributed a prognostic value to the Kafka hemolysin reaction. Kaltenbach (39) believes, on the other hand, that the best prognostic value should be attributed to the mastic reaction (Kafka modification) which in favorable cases changes its paretic curve into a syphilitic one. Other authors are very skeptical on this point and U. Fleck (22), for instance, asks for further investigations of the subject, while York points out that from the prognostic viewpoint much more importance is to be attached to the clinical manifestations than to alterations of the spinal reactions.

The review of the literature shows us that papers devoted entirely to the study of the serology following malaria treatment are very few, as the majority of writers have given only secondary attention to the subject. This circumstance has stimulated us to consider the question of the serology from a detailed point of view. Another reason for considering this problem as we did is that many authors seem to have neglected the important factor represented by the time element, i. e., the period which elapses between the malaria treatment and the last spinal fluid examined. As a fact, some of the authors have drawn their conclusions by examining fluids taken a few months after the malaria inoculation while some others took into consideration the results of spinal puncture performed a long time after treatment. The differences in the

time element might explain the discrepancies in the results as well as the lack of parallelism between the serological and clinical results.

From the material of this hospital, we have selected for our paper those cases which, due to repeated spinal punctures, enabled us to judge the real extent of the improvement, as well as to predict the eventual course. Table I indicates the number of the cases divided according to the date of the malaria treatment.

TABLE I

NUMBER OF CASES AND DATES OF MALARIA INOCULATION

Year	Jan.	April	May	June	July	Aug.	Oct.	Nov.	Dec.	Total
1922	..	..	..	..	..	..	..	..	2	2
1923	..	15	14	2	8	6	..	..	..	45
1924	..	..	..	..	..	..	8	..	10	18
1925	3	4	..	..	..	..	15	2	1	25
1926	5	..	..	..	..	..	..	..	..	5
									Total	95

The table shows that the oldest cases were treated in December, 1922, while the most recent ones have received the malaria inoculation not later than the past January. Our observations can then be extended to a period of over three years.

Table II is a general prospective view of the serological modifications at different intervals of time following the malaria treatment. The interval of time is based on the last spinal puncture and has been divided into five groups, i. e., within six months, twelve, eighteen, twenty-four and thirty-six months. The data reported in Table II show clearly how the serology gradually improves with the increase of the time which has elapsed after the malaria treatment. Examining now every single component of the serological formula, the following considerations can be set forth.

CEREBROSPINAL FLUID

Wassermann reaction.—Within the first six months twenty of the cases considered, i. e., eighty per cent. of the cases, showed an unchanged reaction while only four cases showed improvement, and only one a negative reaction.

TABLE II

SEROLOGICAL MODIFICATIONS AT DIFFERENT INTERVALS OF TIME FOLLOWING THE MALARIA TREATMENT

Time Intervals	*No. of cases*	*Blood Wassermann*	*Cerebrospinal Fluid — Wassermann*	*Cells*	*Globulin*	*Colloidal gold*
Within 6 months	25					
Unchanged		11	20	8	8	20
Improved		7	4	12	14	5
Negative (1)		7 (2)	1	5	3	0
Within 12 months	14					
Unchanged		3	5	7	4	7
Improved		4	6	3	8	7
Negative		7	3	4	2	0
Within 18 months	20					
Unchanged		3	6	5	8	8
Improved		6	7	10	10	12
Negative		11	7	5	2	0
Within 24 months	11					
Unchanged		0	0	0	5	1
Improved		1	5	6	5	10
Negative		10 (2)	6	5	1	0
Within 36 months	23					
Unchanged		2	2	1	4	3
Improved		1	5	10	12	18
Negative		20	16	12	7	2

(1) For cells, negative signifies normal number.
(2) One case was negative before inoculation.

Within twelve months an improvement is seen in the percentage of the modified cases. As a fact, six of the fourteen cases, that is to say 42.6 per cent., showed improved reaction and three (22.8 per cent.) a negative reaction.

Within twenty-four months the serological modifications are still more striking as all of the eleven cases (one hundred per cent.) showed improvement, six of which (fifty-four per cent.) showed a negative reaction.

Finally within thirty-six months twenty of the twenty-two cases showed improvement (ninety per cent.), sixteen of which (68 per cent.) give a negative reaction.

Cells.—Here the changes are more intense and more rapid as, within the first six months, sixteen of the twenty-five cases (sixty-four per cent.) already show an improvement, with a reversal to the normal in five of the cases. Although the proportion of the improved cases from the cytological point of view is not so high within twelve months, the improvement becomes higher within eighteen months, at which period it reaches seventy-five per cent., and successively within twenty-four and thirty-six months all the treated cases, with the exception of one, showed a marked improvement and fifty per cent. of the cases have reversed to the normal.

Globulin.—The improvement in the globulin content is less marked than for the pleocytosis as the initial improvement often remains stationary for a certain time. However, a slight tendency toward a gradual diminution of the globulin content can be gradually seen, for within eighteen months the improved cases represent sixty per cent. of the total and within thirty-six months the proportion is still higher (81.7 per cent.) while 30.8 per cent. of the cases show a reversal to the normal.

Colloidal gold reaction.—The colloidal gold curve appears to be one of the most resistant, and according to our own data it is even more resistant to treatment than the Wassermann reaction itself. Within the first six months, twenty of the twenty-five cases (eighty per cent.) show no changes in the paretic curve and only twenty per cent. of the cases show an improvement. Within twelve months fifty per cent. of the cases, a proportion higher than for the Wassermann reaction, show still an unchanged curve. It is only within twenty-four months that the proportion of the improved cases increases considerably, ten of the eleven cases showing the improvement mentioned. Finally within thirty-six months 85.5 per cent. of the cases show improvement and a few of them a complete reversal to a normal curve.

Blood Wassermann.—The improvement in the Wassermann reaction of the blood is so rapid that already within six months thirteen cases show improvement, in six of which a negative reaction is obtained. The proportion of the improved cases continues to increase within twelve months and eleven of the fourteen are favorably influenced, seven of which show reversal to the normal. The results are more striking within twenty-four months as in all the cases, with the exception of one, the Wassermann reaction became negative. Within thirty-six months 81.7 per cent. of the cases show a negative blood Wassermann.

As examples of the different series, we give in the following tables some of the cases, with a detailed report of the serological results at different intervals of time. In Table III we have taken into consideration the changes noted within the first thirty days, namely, after six, eight, eleven and twenty days following the appearance of the first chill.

From the results reported in this table, two conclusions are indicated: The first is that the malaria treatment in a very early stage has a favorable influence on the pleocytosis. Six days after the appearance of the chills there is already an appreciable reduction in the number of cells, and in the reported case they fell from 37 to 27 per cubic millimetre. The improvement in this field becomes the more pronounced and a few days later (eight days) shows a reduction from 45 to 18, and after twenty days the number of cells fell to within the normal limits. The pleocytosis it appears then is undoubtedly the first component of the serology to improve after the malaria treatment.

The next consideration is that in the early stages following the malaria treatment some of the reactions tend to become worse rather than better. Some of the authors, as for instance Claude and Targowla, have reported a few cases in which the serology and especially the Wassermann reaction of the serum which was negative before the malaria inoculation, became positive following the treatment. No author has, however, reported this type of changes in such early stages as is here reported by us. In Case IV the Wassermann reaction of the blood, which was moderately positive before the treatment, became strongly positive, and, in addition, the colloidal gold curve which first was 3321100000 became typically paretic, 5554321000. The same might be said for the blood Wassermann in Case V.

Table IV shows the serological changes in a few cases one month after the malaria treatment. From this table the same conclusions are indicated as for the earlier stages. The main change in the serological picture continues to be a very considerable improvement in the pleocytosis.

In Table V the serological modifications six months after the malaria treatment are reported. At this period, besides the striking improvement of the pleocytosis already mentioned in the earlier stages, an improvement also becomes evident in the Wassermann reaction. Case IV is the case reported in Table II which, within six months, showed a negative Wassermann reaction of the cerebrospinal fluid. The globulin content shows also a tendency to a slight improvement. The changes occurring in the colloidal gold curve are too slight to be discussed.

In Table VI it may be seen clearly that the improvement gradually involves all of the components of the serological picture. Out of the fourteen cases, the Wassermann reaction was improved in eleven in the blood and nine in the cerebrospinal fluid. In three of these nine, the reaction became negative in the cerebrospinal fluid. Fifty per cent. of the cases also show improvement of the colloidal gold curve.

Table VII shows the details of the serology in some cases up to eighteen months after the malaria treatment.

During this period the serological modifications are very typical. The blood Wassermann is negative in more than fifty per cent. of the cases and the cerebrospinal fluid Wassermann is very favorably influenced. Seven of the twenty cases show negative reactions of the fluid. The colloidal gold reaction is strongly influenced in some of the cases and sixty per cent. of the cases show general improvement. The pleocytosis gradually improves, many of the cases having a cell count extremely close to the normal. The globulin content also tends to approach the normal in the improved cases.

(To be continued)

Historical Medicine

Leonardo Da Vinci, Anatomist and Physiologist

LEOPOLD VACCARO, M.D.
Philadelphia, Pa.

(*Continued from page* 479)

HOW THE BODY OF THE ANIMAL CONTINUALLY DIES AND IS RENEWED

On this physiological topic the physiologist Leonardo says:

"The body of anything whatsoever that receives nourishment continually dies and is continually renewed. For the nourishment cannot enter except in those places where the preceding nourishment is exhausted, and if it is exhausted it no longer has life. Unless therefore you supply nourishment equivalent to that which has departed, the life fails in its vigor; and if you deprive it of this nourishment, the life is completely destroyed. But if you supply it with just so much as is destroyed day by day, then it renews its life just as much as it is consumed; like the light of the candle formed by the nourishment given to it by the fat of the candle, which light is also continually renewed by swiftest succor from beneath, in proportion as the upper part is consumed and dies, and in dying becomes changed from radiant light to murky smoke. And this death extends for so long as the smoke continues; and the period of duration of the smoke is the same as that of what feeds it, and in an instant the whole light dies and is entirely regenerated by the movement of that which nourishes it; and its life receives from it also its ebb and flow, as the flicker of its point serves to show us. The same process also comes to pass in the bodies of the animals by means of the beating of the heart, whereby there is produced a wave of blood in all the veins, and these are continually either enlarging or contracting, because the expansion occurs when they receive the excessive quantity of blood, and the contraction is due to the departure of the excess of blood they have received; and this the beating of the pulse teaches us, when we touch the aforesaid veins with the fingers in any part whatsoever of the living body. But to return to our purpose, I say that the flesh of the animals is made anew by the blood which is continually produced by that which nourishes them, and that this flesh is destroyed and returns by the mesaraic arteries and passes into the intestines, where it putrefies in a foul and fetid death, as they show us in their deposits and steam like the smoke and fire which were given as a comparison." (Windsor MSS. *Dell' Anat.* Fogli B 28 r.)

HOW THE FIVE SENSES ARE THE MINISTERS OF THE SOUL

"The soul apparently resides in the seat of the judgment, and the judgment apparently resides in the place where all the senses meet, which is called the common sense; and if it is not all of it in the body, as many have believed, but is all in this part, it would not have been necessary for the instruments of the senses to come together in concourse to one particular spot; rather would it have sufficed for the eye to register its function of perception on its surface, and not to transmit the images of the things seen to the sense by way of the optic nerves; because the soul—for reasons already given—would comprehend them upon the surface of the eye.

"Similarly, with the sense of hearing, it would be sufficient merely for the voice to resound in the arched recesses of the rocklike bone, which is within the ear, without there being another passage from this bone to the common sense, whereby the said mouth might address itself to the common judgment.

"The sense of smell also is seen to be forced of necessity to have recourse to this same judgment.

"The touch passes through the perforated tendons and is transmitted to this sense; these tendons proceed to spread out with infinite ramifications into the skin which incloses the body's members and the bowels. The perforating tendons carry impulse and sensation to the subject limbs; these tendons passing between the muscles and the sinews dictate to these their movement, and these obey, and in the act of obeying they contract, for the reason that the swelling reduces their length and draws with it the nerves, which are interwoven amid the particles of the limbs, and being spread throughout the extremities of the fingers, they transmit to the sense the impression of what they touch.

"The nerves with their muscles serve the tendons, even as soldiers serve their leaders, and the tendons serve the common sense as the leaders their captain, and this common sense serves the soul as the captain serves his lord.

"So, therefore, the articulation of the bones obeys the nerve, and the nerve the muscle, and the muscle the tendon, and the tendon the common sense, and the common sense is the seat of the soul, and the memory is its monitor, and its faculty of receiving impressions serves as its standard of reference.

"How the sense waits on the soul, and not the soul on the sense, and how where the sense that should minister to the soul is lacking, the soul in such a life lacks conception of the function of this sense as is seen in the case of a mute or one born blind." (Windsor MSS. *Dell' Anat.* Fogli B 2r.)

OF THE MUSCLES WHICH MOVE THE TONGUE

"No member needs so great a number of muscles as the tongue—twenty-four of these being already known apart from the others which I have discovered; and of all the members which are moved by voluntary action this exceeds all the rest in the number of its movements.

"And if you shall say that this is rather the function of the eye, which receives all the infinite varieties of form and color of the objects set before it, and of the smell with its infinite mixture of odours, and

of the ear with its sounds, we may reply that the tongue aso perceives an infinite number of flavors both simple and compounded; but this is not to our purpose, for our intention is to treat only of the particular movement of each member.

"Consider carefully (1) how the movements of the tongue with the help of the lips and teeth, the pronunciation of all the names of things is known to us; and how, by means of this instrument, the simple and compound words of a language arrive at our ears; and how these, if there were a name for all the effects of nature, would approach infinity in number, together with all the countless things which are in action and in the power of nature; and these would not be expressed in one language only, but in a great number of languages and these also would tend to infinite variety, because they vary continually from century to century, and in one country and another, through the intermingling of the peoples, who by wars and chance or deliberate experiments succeeded in creating the smallest thing which can be created by Nature; and indeed this generation deserves unmeasured praises for the serviceableness of the things which have been invented for the use of men, and would deserve them even more if they had not been the inventors of noxious things like poisons and other similar things which destroy the life or the intellect; but they are not exempt from blame in that by much study and experiment they are seeking to create, not, indeed, the meanest of Nature's products but the most excellent, namely gold, which is begotten of the sun, inasmuch as it has more resemblance to it than to anything else that is, and no created thing is more enduring than this gold. It is immune from destruction by fire, which has power over all the rest of created things, reducing them to ashes, glass, or smoke. If, however, insensate avarice should drive you into such terror, why do you not go to the mines

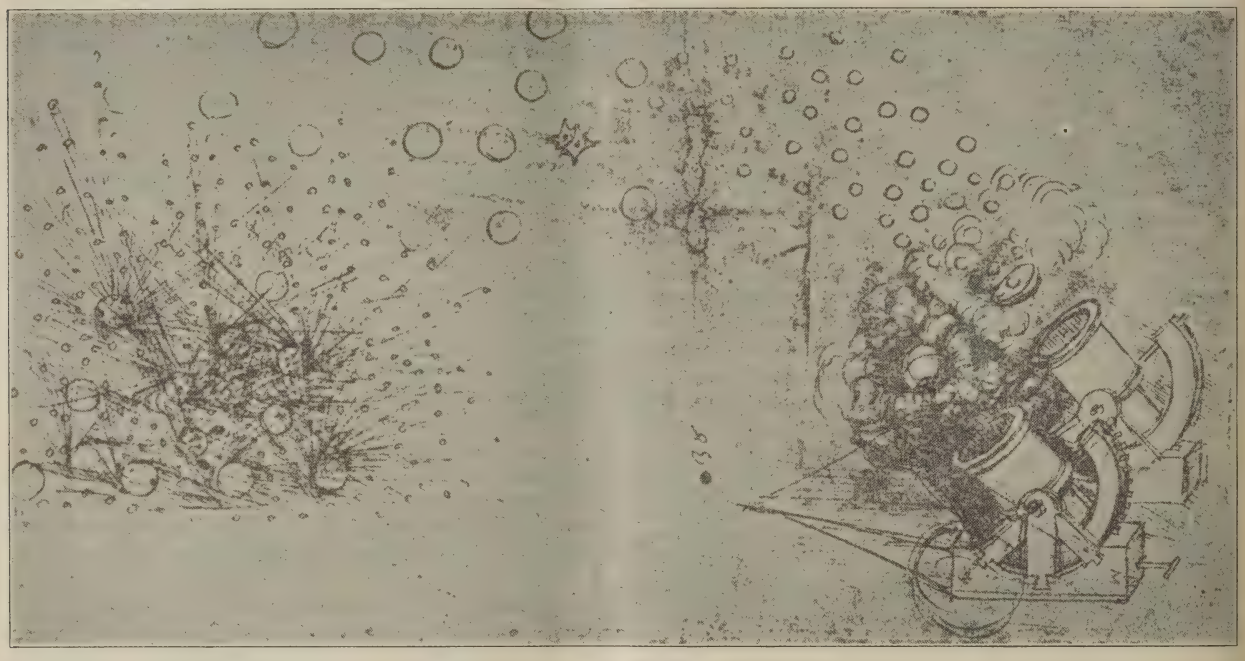

Fig. 5.—Mortar for throwing bombs and shrapnel

other mischances are continually becoming mixed with each other; and these same languages are liable to pass into oblivion, and they are mortal like all the rest of created things; and if we grant that our world is everlasting we shall then say that these languages have been, and still must be, of infinite variety, through the infinite number of centuries which constitute infinite time.

"Nor is this true in the case of any other sense; for these are concerned only with such things as nature is continually producing, and she does not change the ordinary kinds of the things which she creates in the same way that from time to time the things are changed which have been created by man; and indeed man is Nature's chiefest instrument, because Nature is concerned only with the production of elementary things, and man produces an infinite number of compounds, although he has no power to create any natural thing except another like himself, that is, his children. And of this the old alchemists will serve as my witness, who have never either by where Nature produces this gold, and there become her disciple?

"She will completely cure you of your folly by showing you that nothing which you employ in your furnace will be numbered among the things which she employs in order to produce this gold. For there is there no quicksilver, no sulphur of any kind, no fire nor other heat than that of Nature giving life to our world; and she will show you the veins of the gold spreading through the stone—the blue lapis lazuli, whose color is unaffected by the power of the fire. And consider carefully this ramification of the gold, and you will see that the extremities of it are continually expanding in slow movement, transmitting into gold whatever they come in contact with; and note that therein is a living organism which it is not within your power to produce." (Windsor MSS. *Dell' Anat.* Fogli B 28 v.)

Giovanni Papini (7) thus speaks of Leonardo's genius: "It seems as though this man whose father and grandfather had been notaries, were possessed of

an atavistic desire to undertake an inventory of the universe." That passion for detail which had dulled the spirits of so many of his successors had seized him all too firmly. In a certain sense he was a positivist long before the time of positivism. For that reason perhaps, he is held in high esteem by our own scientists. Every now and then one of these gentlemen discovers that Leonardo was the founder

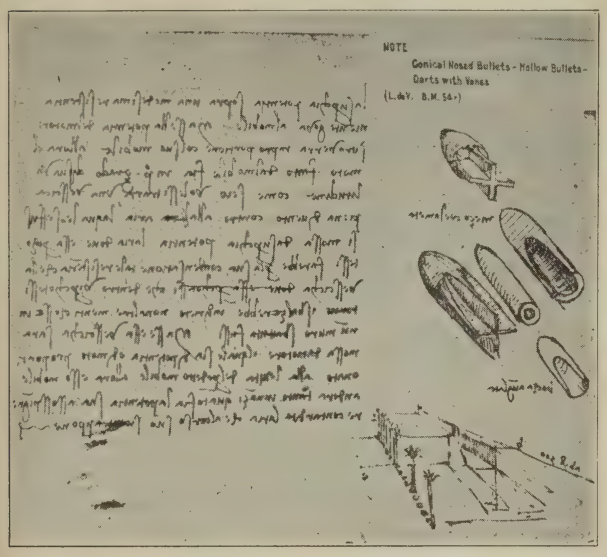

Fig. 6.—Cylindrical bullets with vanes cut out of the shaft.

of some science or other, and salutes him as the father and maker of the experimental method.

"He is more of a scientist than artist. Even his painting, though he poured into it the treasure of his dreams, was to him primarily a form of science, determined to reproduce the aspects of Nature with the most scrupulous fidelity. All of his studies, even those which were directly related to his work as painter, led in reality toward a complete knowledge of the universe. And his constant preoccupation, which wins the plaudits of the scientists, tend, on the contrary, to repel those who love aesthetic and metaphysical unreality, as I do."

ON BOTANY

Over one hundred and fifty years ago Charles Bonnett, the Genevan botanist, introduced the socalled doctrine of phyllotaxy, that is to say, the exact observation of the relative position of the leaves on the stalk. To the most widely spread form of this position of this relative position he gave the name of Quincux; in this the sixth leaf after the stalk has been twice encircled invariably stands above the first; accordingly, every cycle of leaves consist of five leaves. This discovery was the result of years of study by an experienced and professed botanist. But two hundred and fifty years earlier Leonardo's artist eye had observed the Quincux, and had drawn it with the most painful care, and that is found in his *Book on Painting.*

LIFE OF LEONARDO DA VINCI

Leonardo was born at Vinci, a Tuscan mountain town, near Empoli, in 1452, the illegitimate son of Ser Piero d'Antonio, a Florentine notary, and Catarina, a peasant woman. His boyhood was spent at the paternal home at Vinci. In 1649 his family moved to Florence, where his father's wealth enabled him to enjoy the very best education which Florence, at that time the intellectual and artistic centre of Italy, could afford, and he speedily became the embodiment of every social and intellectual charm. He was singularly handsome in person, powerful in physique, persuasive in conversation; and his mind was possessed of an insatiable love of knowledge and research, which proved the controlling factor of his life. Before taking up painting, he began the studies in mechanics and in the natural sciences which went hand in hand with his artistic activity throughout his life.

About 1466-69 he became the pupil of his father's friend, Andrea del Verrocchio. In 1472 he was entered into the painters' guild of Florence and in 1476 he is still mentioned as Verrocchio's assistant, but in 1478 he was working as an independent master. From Verrocchio, Leonardo learned modelling as well as painting; but nothing of his work during apprenticeship has survived. According to Vasari he painted an angel in Verrocchio's *Baptism of Christ,* with such skill that his master resolved to cease painting. The statement concerning Verrocchio is wrong, but it is quite possible that the angel in question is by Leonardo. The account of the terrifying shield upon which the artist painted all manner of monstrosities acquired from his studies of lizards, serpents, worms, etc., may have some basis of fact; but the *Head of Medusa* is certainly a forgery based on Vasari's description. The *Annunciation,* too, in the same gallery, is by a member of the school of Verrocchio; but a genuine painting of this subject by Leonardo is in the Louvre.

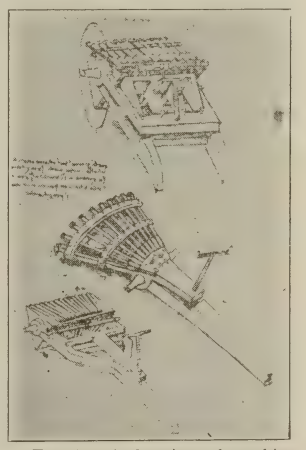

Fig. 7.—A drawing of machine gun.

Fig. 8.—Sketch of flying machine.

In 1478 he was commissioned by the Signorio of Florence to paint a picture for the Chapel of St. Bernard, in the Palazzo Pubblico. His first masterpiece, *The Adoration of the Kings,* which is in an unfinished state, survives in the Uffizzi, was ordered in 1481, for San Donato a Scoppello, Florence. The figures have not for the most part advanced further than the grounding; but they reveal a fine scheme of composition, and dramatic action.

(To be concluded)

Early Remedies for Hydrophobia

KATHRYN MADDREY
Austin, Texas

Since Louis Pasteur formulated his preventive treatment of one of man's most dreaded diseases, hydrophobia, in the early eighties, further progress made has been largely that of improving the means of applying the treatment first laid down by the great French scientist, according to physicians. Before that time there were many treatments in common use which were often credited with remarkable results. These long ago passed out of common knowledge.

The Pasteur method is still astounding, and to the lay mind sometimes incomprehensible. The old practices, though hopelessly out of date so far as their medical value is concerned, are still interesting, however. In the *American Museum, or Universal Magazine,* a journal published in Philadelphia in 1790, appears an interesting account of the treatment of the disease in that day.

The author of the article says, regarding his remarks, "If by the mode of treatment here laid down, a single life shall be saved, it will be a source of the highest satisfaction to the author, who is actuated by a desire to spread the knowledge of and to excite the attention of physicians toward the disorder, the most dreadful to which humanity is subject."

"The medicine alluded to," the article continues, "composed of musk and cinnabar, is commonly called the 'tonquin or East India remedy,' as it first came from that country where it was said to have been given with great success which induced physicians in other parts of the world to try it. But from their numerous accounts, by no means with that success which the credulous East Indians had said.

"Musk, if produced genuine, certainly would prove useful in this disease by its stimulating power, but this is seldom the case, for from its great scarcity and consequent high value, it leads apothecaries and others greatly to adulterate it. But even where it is pure, its union with an inert substance such as cinnabar would greatly diminish its virtues and interrupt or totally destroy its operation on the human body. I therefore think that the use of it ought to be laid aside, and our reliance placed upon other medicines by which more certain effects would be produced.

"Sir Hans Sloan first, and after him Dr. Meade, warmly recommended the famous Dampier's powder composed of ash colored ground liverwort and black pepper. But it was always found to be ineffectual where the disease for which it was given existed.

"The Ormskirk medicine, likewise, which for some years afterwards gained credit in England, soon fell into disrepute upon the death of several persons in various parts of Great Britain who, after being bitten by animals really mad, took the medicine with the fullest expectation of a certain cure, but were seized with the hydrophobia and died raving mad.

"Copper, which even in the dose of a few grains acts as a powerful emetic and purgative, was also some years ago much celebrated in Germany for its good effects on this disorder. The reputation, however, of this poisonous metal was but short lived, and now we hear no more of it."

That quack medicines flourished then even as now is shown by the writer's remarks on a presumably valuable remedy which had been in the possession of a certain family for many years. Notices similar to the following, which was taken from the same publication, are found today in many papers.

"In this city a man publishes an account every summer of his having an infallible cure for this disease composed entirely of 'vegetables,' which are to be boiled in milk and taken internally. And in order to make it have more weight with the vulgar, he says, 'the receipt has never been out of his family, but descended from father to son for a century past.' I have never heard of a cure performed by this man and his vegetables, but know that he failed in an attempt in the Pennsylvania Hospital some years ago where as fair a trial was given as he wished for.

"It was only the most superstitious reverence of Dr. Boerhaave's name and authority by his pupils and others that made the method laid down by him be so long pursued of treating the disorders as of a highly inflammatory nature, and of course ordering the most powerful evacuations, as it was always found to be very destructive and attended with the most fatal consequences to those who had the misfortune to be the subject of this injudicious mode of treatment.

"The only certain means by which this disease can be presented is either to furnish an outlet for the poison occasioning the disease by exciting an inflammation and a suppuration in the wound as soon as possible after the bite has been received, or by invigorating the system, render it superior to the powerful sedative nature of the poison, thereby preventing the debility consequent on its being induced into the system. It is of no consequence by what means this inflammation is effected, so that the different applications insisted upon by different practitioners and others may all be proper enough, for upon enquiry it will be found that they are all of a stimulating nature. For such length of time has the propriety of this practice been known that I observe Aetius recommends it. Celsus likewise advises cupping and applying the actual cautery to the wound. Dr. Boerhaave, in order to do the business effectually, desires a suppuration to be kept up from the bitten part for six months, and to be continually fomented with a pickle made of vinegar and salt.

"Upon this principle, that is, of exciting an inflammation, I conceive the 'solution of the common caustic in water,' mentioned in the *Museum* for February, 1787, can only act, and also the 'finely powdered common salt,' so highly spoken of by Dr. Gale in his letter to the medical society of New Haven, Connecticut, which is inserted in the number of your work for December of the same year. Dr. Haygarth's method, of a long continued stream of cold water from the spout of a tea kettle in the greatest number of instances can only be explained in the same manner, so it is not entitled to more faith than the rest of the above topical remedies except where the wound happens to be received on the face or near some large

bloodvessel where a dangerous hemorrhage might be expected, or deformity ensue from the enlargement, or scarification of the part in which case the plan of ablution may be used with great advantage.

"Of all the applications, however, that have been recommended, the use of strong mercurial ointment has been attended with the greatest success. Having therefore dilated and scarified the wound, two drachms of the ointment may be rubbed into the sore and the same quantity round the throat, and two or three grains of calomel given every day combined with opium, to prevent it running off by the bowels.

"This practice must be continued until the mouth be affected and the sore considerably inflamed when the use of the calomel may be laid aside for some days, and if necessary a purge given that the effects of the mercury may abate.

"This practice must be occasionally repeated for four or five months at least, during which time the wound ought by no means be suffered to heal, but a copious suppuration made to flow from it. After which, if no symptoms of the hydrophobia appear, the patient may be pronounced out of danger.

"But in case we should be called in late when the wound is nearly or altogether healed and the disease has actually appeared, the above mode of treatment should be strictly pursued, though with much greater expedition. The part bitten should be dilated and scarified, the quantity of both mercurial ointment and calomel should be increased, to the former of which some oil or spirit of turpentine may be added to increase its stimulant effect. And as fear tends to debilitate and increase the disease as a placid and joyful state of temper contributes to its removal, the passions of the patient ought by no means to be ruffled, but the utmost confidence inspired in his mind.

"I am very readily disposed to embrace the opinion of our learned and ingenuous countryman, Dr. Rush, in ascribing both tetanus and hydrophobia to the same proximate cause. We have numerous and well attested instances on record of the latter disorder being produced in persons who have not been bitten by a mad animal, but in whom it was occasioned by excessive fatigue and labor, violent and depressing passions, chagrin, fear, grief, anger, and the like; causes which are powerfully debilitating.

"I am, therefore, fully persuaded that the plan of treatment to be pursued in both diseases ought to be the same, that is, giving medicines to strengthen and invigorate the system.

"Of the good effects of tonics in the tetanus, Dr. Rush has given incontestable proof, but whether they will prove equally serviceable in the hydrophobia, he has not as yet determined. The strong analogy, however, between the two diseases renders the probability very great. The liberal use of opium, wine and bark is very advisable, therefore, as the surest means of preventing the disease, and also of curing it."

How Insanity Was Treated in the Middle Ages

In the Middle Ages the devil was a very definite reality. Not only his moral—or rather his immoral—qualities were catalogued, but his corporeal manifestations were known and his psysiognomy was well established. All his depicters were as well agreed in this matter as are our contemporary artists on Santa Claus.

All insanity was looked upon as being an obsession by the devil. The terms upon which one sold his soul to the devil were clearly understood and the proper methods of exorcising him were clearly set forth in many books by various authors. This is most interestingly set forth in *The Devil, an Historical, Critical, and Medical Study,* by Garcon and Vinchou, recently published in Paris.

One of the medicaments recommended for the treatment of those "possessed of the devil," as the insane were designated, was the application of an oil made according to the following formula: Mix equal parts of rue, sage and fennel with olive oil and holy water. First boil the mixture and then have it blessed. During its inunction the priest should invoke the aid of God, the creator of the world, against the demon infecting the patient, and against the phantoms which it produces. The priest also prays that the patient may be cured of the weakness following the expulsion of the demon.

Another contains the flowers of scoparius, of white marrubium, of nettle and of rue. Scoparius is still employed as a heart tonic and, according to the researches of Henri Leclerc, marrubium is useful as an antispasmodic. Therefore, while this formula is wholly empirical it is still in accord with modern views and might still be administered today to a maniac.

The treatment should be given in a church or other building dedicated to God. But in no case should it be carried on in the home, because of the presence there of women who, it is believed, are prone to fall under the dominion of the devil.

We reproduce from the book a wood cut from *The Life of the Saints* printed in Augsburg in 1488. —*Aesculape.*

Editorial Articles

THE MORAL SENSE IN PSYCHIATRY

The general practitioner, busying himself with childbirth, measles, pneumonia, arteriosclerosis and enlarged prostate, has but little time to concern himself with abstract questions of ethics. Bound himself by a somewhat rigid code he but seldom meets with problems in his professsional relationship which cause him much uncertainty and his conduct tends to become rigidly conditioned. In the conduct of his patients he recognizes, albeit with a somewhat greater tolerance as a rule than the layman, the good and the bad, the honest man and the sneak, the hero and the craven. Thus, in his discussions with his colleagues and occasionally in his contributions to the journals we meet with expressions of approval or of condemnation.

But when we come to consider the psychiatrist a different attitude should prevail. For here we have one who is concerned with human behavior. He has not progressed far into his subject before he learns that any act is not a solitary circumstance but the end result of a billion causes. He learns that the person starts life with an equipment derived from a phylogenetic history of millions of years and that from birth onward he is subjected to countless influences, moulding and directing his course. Knowing this, he is not inclined either to praise or to blame. Nor is it in his province to do either. His function it is to study human behavior in its ordinary manifestations and in its usual aberrations with the idea of dealing adequately with those forms which are inimical to the health of the individual or the welfare of society. To the psychiatrist deviations from the norm should be scientific facts. He should recognize them as behavior problems purely and entirely unconnected with ethics. Thus he does not speak of a patient as being bad, or vicious or mean, or use any other adjective implying censure.

Probably in no aspect of human behavior is this caution more necessary than in dealing with sexual problems. It is quite common to read descriptions of sexual perversions in supposedly scientific magazines and find them full of such terms as horrible, disgusting, depraved, and others.

This is of course easily translated by the initiated. Such and such a thing is disgusting to me, that is, it arouses my disgust, because it has an emotional appeal to me which I must negative by an equally strong and antipathetic emotion. All of which is from the primer of psychopathology and would not matter one way or the other except that the constant insistence upon a moral standard in dealing with such subjects influences in time wouldbe students and deters them from investigation.

Let us then avoid all such critical terms in medicine. Facts exist ineluctably as the results of causes and modes of human behavior are as much scientific facts as the action of sulphuric acid on iron. They should be described, discussed and interpreted if possible, but not pilloried.

PERIL OF THE STREET

Among the countries and cities of the world this country and New York city hold an unenviable reputation for the large number of road and street accidents chiefly consequent upon the immense volume of motor traffic in general and automobiles in particular.

However, the most recent statistics in this respect from Great Britain, London and other cities show that accidents are increasing there at a rapid and alarming rate. In London alone the increase has been notable. For example, in 1909 in the London metropolitan police district there were only 303 fatal accidents, of which 171 were due to mechanically propelled vehicles. In 1924 the total rose to 665 and in 1925 to 833, the proportion attributed to mechanically propelled vehicles last year being 765, or more than four times more than in 1909. The same tale prevails for Great Britain as a whole.

Horse drawn vehicles are so little used now that they account for only a small proportion of the street accidents which occur today.

Motors of every description have been increasing at an enormous rate, nearly one hundred thousand a year. And it may be noted that while that increase has gone on the proportion of fatalities to vehicles has, it has been computed, remained fairly constant at a fraction over two per thousand. Accordingly there is hope that in due time improvement may set in.

Compared with street or road, some other forms of travel seem to be quite safe. It is certainly true that in 1924, the last year for which returns are available, only forty-two persons were killed and 683 injured on the British railways so that in view of the number of passengers carried there would appear to be good foundation for a remark made by the British Minister of Transport, that the chances of being killed on the railway are one hundred and sixty-five million to one compared with ten thousand to one in the London streets. It was said before the British Coal Commission that the Londoner's chances of accidents are about equal to those in a coal mine.

If this be so the New Yorker compares very unfavorably with the coal miner with regard to the risk he runs to life and limb when walking or driving in this great city. At sea the loss of life averages about two hundred and forty a year, and although flying is held to be especially dangerous, there were last year only forty-two accidents involving fifty-seven deaths which almost makes one believe that it is safer to fly than to travel on a motor cycle for instance.

As regards the possibility of reducing the number of street accidents there have been various suggestions. One expert has recommended the adoption of a new jury system for investigating the cause of vehicular accidents and the best means for preventing their recurrence, just as inquiries are made into the cause of railway accidents. There is a tendency in this country in the case of an accident in which a pedestrian plays one of the principal parts to lay the blame on the one afoot. The truth appears to be that both driver and pedestrian need to exercise more care than is sometimes exercised, but as the pedestrian is necessarily the greatest sufferer in the case of collision, it seems that it should be made incumbent on the driver of an automobile to be especially careful and to be severely punished if he is careless. The problem of the streets and roads is grave and means should be sought and put into practice whatever the cost may be to minimize their risks.

SOME AMERICAN PHYSICIANS AND SURGEONS

In the *Peaks of Medical History,* written by Dr. Charles L. Dana, published by Paul B. Hoeber, Inc., New York, is given a brief history of the evolution of medicine. As Dr. Dana succinctly says, he emphasizes the high spots in the evolution of medicine, so that a student may in a short time obtain a visualization of the subject as a whole, and thus get a background upon which he can work out details in accordance with his interests and tastes.

The author has succeeded admirably in his avowed object and has produced a work which is at one and the same time instructive and fascinating. He draws attention to a great English clinician, Thomas Willis, 1621-1675, a contemporary of Sydenham, and who really did more original work than that great observer. Willis, of whom little is heard, first described typhoid and puerperal fevers, dementia paralytica and myasthenia gravis. He was a great anatomist, and described the circle of Willis in the brain and named the cerebral nerves.

Dana points out that in Boston, the name of Warren is associated closely with the history of American surgery and the technical achievements of those early days. Dr. John Warren, 1753-1815, rendered service in the Revolution and was the first professor of anatomy and surgery in the Harvard Medical School, of which he was really the founder in 1783. His son, John Collins Warren, 1778-1856, was a pioneer in orthopedic surgery and a very successful operator. He was founder of the Massachusetts General Hospital in 1811 and was the surgeon who cooperated with Morton when he introduced ether.

In Philadelphia the name of Dr. Benjamin Rush, 1745-1813, stands out as the leading physician of that city from the time of the Revolution until his death. Rush was a man of unusual activity in social and political life, as well as in the teaching and practise of medicine. He was the first in this country to write systematically on mental disease. He is widely known in history as one of the signers of the Declaration of Independence.

A man who was equally famous in the practise of his profession was Philip S. Physick, 1768-1837. Physick was a very ingenious and skilful surgeon and is known as the father of American surgery, but he did not write concerning his work.

In the early part of the nineteenth century there was an interesting and distinguished group of medical men in New York. The earliest of them was Samuel Bard, 1742-1821. He was the founder of New York Hospital and was physician to General Washington. His father, Dr. John Bard, was also an important man of his day, having among other things instituted the Pest House on Bedloe's Island.

Dr. David Hosack, 1769-1835, was born in New York of Scotch descent. He was prominent as a teacher and held six professorships during the latter sixteen years of his life. He helped to organize the dispensary system of New York and founded the Humane Society.

Dr. Valentine Mott, 1785-1865, was one of the greatest of New York surgeons. Mott was active in the organization of the medical schools of this city. At the beginning of the century there were two medical colleges here; these became united under Columbia University in 1811. In 1826 the medical faculty revolted and founded the Rutgers Medical College, which lasted about five years. Dr. Mott was especially famous for ligating the important arteries of the body. He is said to have been the first man in this country to tie the innominate artery and he ligated with success the common carotid artery. He is said to have done 132 important ligations. He, like Dr. Physick, did not contribute to literature.

Dr. John Francis, 1789-1861, wrote on dipsomania and insanity, but his most important work was a history entitled *Old New York.* Dr. W. E. Horner, 1793-1853, of Philadelphia, was an able teacher of anatomy and the author of a well known textbook. The world renowned Dr. Oliver Wendell Holmes, of Boston, 1809-1894, whose literary work has over-

shadowed his fame as a physician, was professor of anatomy at Harvard University and the earliest defender in this country of the view that puerperal fever is a communicable infection. Dr. Samuel D. Gross, 1805-1884, of Philadelphia, was a great surgeon and the author of the first treatise on pathological anatomy. He also wrote *The Lives of Eminent American Physicians and Surgeons,* published in 1861.

Dr. Dana has deserved well of the medical profession of all countries by writing *The Peaks of Medical History.*

THE SURGERY OF RICKETS

The cause of rickets, if not known precisely for practical purposes, seems to have been discovered to such an extent that it can be largely prevented. It is not lack of light alone or improper diet alone that causes it, but a combination of these. Rickets can be prevented in children with a tendency in that direction by giving them a sufficiency of light and fresh air, giving them a diet containing the organic factor concerned in the calcification of bone and an adequate amount and correct balance in the diet of the salts of calcium and phosphorus. Moreover, cod-liver oil is the most dependable single agent for cure.

While rickets can be prevented, much rickets will not be prevented and for some time to come the correction of deformity due to the disease will remain a task for the orthopedist. At a meeting of the Manchester Medical Society held on March 31st last, Mr. Henry Platt, a leading orthopedic surgeon of that city, discussed the problem of the prevention and cure of deformity proceeding from rickets. He pointed out that many of the measures used today in the treatment of rachitic deformities had undergone little modification since their introduction years ago. At the present time operative intervention in rickets was being placed on a sounder basis. A deformity corrected in the stage of florid rickets was always likely to recur, so that some criterion of the activity of the disease was needed. This had now been provided as a result of a study of radiograms of the epiphyses in the various stages. Other advances had been made in the study of rickets which rendered the work of the surgeon more sure and more safe.

He pointed out that rachitic deformities which called for the attention of the surgeon usually affected the lower limbs, and of these there were three main types—bow legs, knock knee and coxa vara. Bow legs were essentially a deformity which showed a tendency to spontaneous rectification and it was rarely necessary to employ any special measures and still less necessary to operate. Knock knee, in contradistinction to bow legs, was usually a progressive deformity and once initiated tended to increase long after rickets had healed. As it was determined chiefly by weight bearing, in the early stage this should be prohibited wherever possible. Under the exceptional conditions of an open air hospital, moderate degrees of rachitic knock knee would disappear without any form of splinting. In ordinary hospital out patient practice it was usual to apply a corrective walking appliance, the best form being the classical knock knee brace of Thomas.

A great many cases of knock knee in older children, however, came for operative correction, and on the whole the results of femoral osteotomy were exceedingly good, provided the aftertreatment was adequate. In the adolescent and young adult it was desirable to employ traction or a Thomas splint for as long a period as possible. This minimized the angulation and overlapping of the fragments and helped to ensure rapid union. Refracture after a femoral osteotomy was not an uncommon experience. In the older patients it was sometimes difficult to reproduce the full mobility of the knee joint in a short time.

Mr. Platt said that coxa vara of rachitic origin could be almost ignored as it was chiefly a deformity appreciable only in radiograms. In the production of spinal deformities rickets was a subsidiary or negligible factor.

Surgery, that is operative surgery, plays no great part in correcting rachitic deformities. Orthopedic attention is called for but the treatment of rickets in youth, young and adult life as well as in childhood appears to largely consist in fresh air, sunlight and appropriate diet.

THE LAKE MOHONK CANCER SYMPOSIUM

The purpose of the symposium on cancer control held at Lake Mohonk, New York, October 20th to 24th, has been stated as that of considering the prevention and cure of cancer from a practical viewpoint, and of expressing in concise language the fundamental groundwork of fact and opinion upon which the collective effort now being made in the United States and other countries for the control of cancer should be continued and extended. It was believed that there were many things that physicians and surgeons could agree upon, and that, if these should be expressed in simple, concise terms, the results would be of great value. The meeting, instigated several months ago through the efforts of the American Society for the Control of Cancer, was most successful from the viewpoints of attendance, both American and foreign, and of publicity through the press, which would undoubtedly have been even greater, had not the Dempsey-Tunney fight and the Florida hurricane taken place at the same time.

The chief results of the conference were sum-

marized by Dr. Welch at a dinner to the foreign guests held in New York at the close of the symposium, at which he said: "The great note struck at the Mohonk symposium was the tremendous importance of the cancer question and the appalling problems which it presents. There was never a time when tuberculosis presented problems of such magnitude. The general public and the medical profession must be aroused to the vital importance of efforts to control cancer. However inadequate our knowledge is today, it is an obligation of the profession to the general community that every effort be made to control this scourge. The community must be taught that all types of cancer are not certainly and inevitably fatal if they are recognized and properly treated at an early stage. Emphasis was placed upon the importance of research work, the need of further additions to our knowledge on the one hand, and equally upon the necessity of applying our existing information for the saving of human lives and suffering. There is no disease to which larger additions have been made to our knowledge than cancer, but, because this knowledge does not reach the public which we are most anxious to reach, this seems trivial. The many papers and discussions will be published, and will make a volume which will be an epochal contribution to our knowledge of cancer."

Obituary

MR. H. W. PAGE, M.B.C.M., F.R.C.S.

London

Mr. Herbert William Page, consulting surgeon to St. Mary's Hospital, London, died at his house in Farnham, Surrey, on September 9th, in his eighty-first year.

Mr. Page was a great surgeon and as surgeon to the London and North Western and Great Western Railways devoted much time to the scientific investigation of the symptoms produced directly or indirectly by injuries received in railway accidents. As one result of his careful study he wrote *Injuries of the Back Without Apparent Mechanical Lesions in Their Surgical and Medicolegal Aspects,* for which he was awarded the Boylston medical prize by the University of Harvard in 1881. His work on *Railway Injuries* appeared in 1893.

He entered the University of Edinburgh in 1864 as a house pupil of James Spence who rejoiced among the students in the cognomen *Dismal Jimmy.* From Edinburgh young Page went to Christ Church, Cambridge, where he graduated in arts and medicine, taking also the degree of master of surgery and being elected a Fellow of the Royal College of Surgeons. He then went to the London Hospital, Whitechapel, where he acted as house surgeon to Jonathan Hutchinson, and came under the influence of two brilliant minds, Sutton who taught him the value of morbid anatomy, and Hughlings Jackson, the founder of modern neurology. Page then went to Vienna and when the Franco-Prussian war broke out he served as an assistant surgeon in the Hessian Division of the German army.

After his return to England he practised for a short time with his father in Carlisle and then came to London. He was appointed surgical registrar at the London Hospital in 1875 and in the next year was made assistant surgeon at St. Mary's Hospital. He was on the staff of this hospital for the rest of his life and assisted to raise the standard of its medical school. He was one of the first London surgeons to recognize the value of Lister's teaching and to adopt it in practice. He was a president of the British Neurological Society, an unusual honor for a surgeon, and was a member of the Council of the College of Surgeons and a member of the Court of Examiners. He retired from active work at the end of 1906.

Page was a skilful operator, and possessed as well a wide and deep knowledge of medicine. He was a man who shunned the limelight but possessed the complete confidence of the profession.

ROBERT G. REESE, M.D.

New York

Dr. Robert G. Reese died at his home in this city, on October 18th, at the age of sixty-one years. He was born in Virginia, where he received his early education. He received his medical degree from New York University in 1891. He specialized in ophthalmology and was for years professor of clinical ophthalmology in Cornell Medical College. Dr. Reese was a Fellow of the American Medical Association and of the American College of Surgeons, a member of the American Academy of Ophthalmologists, the Medical Association of New York, and of Phi Beta Kappa.

WILLIAM S. BIGELOW, M.D.

Boston, Mass.

Dr. William S. Bigelow, who died at his home in Boston on October 6th at the age of seventy-six years, was for more than half a century a leading authority on art, a distinguished author, and a life long friend of Senator Henry Cabot Lodge. He was a graduate of Harvard Medical School and lectured in that school from 1879 to 1881 but soon retired from active practice devoting his time to the study of the arts.

He was a student of Buddhism and published a volume on *Buddhism and Immortality.* He made the finest collection of Oriental art in existence, except that of the Japanese government. This he presented to the Boston Museum of Fine Arts in 1911.

Dr. Bigelow was a member of the United States Assay Commission, the Massachusetts Medical Society, and the Boston Society of Medical Sciences. He was Commander of the Imperial Order of the Rising Sun, a Japanese organization; a trustee of the Museum of Fine Arts, a director of the new Boston Music Hall, a Fellow of the American Academy of Arts and Sciences and a member of the Asiatic Society of Japan, the American Oriental Society and similar organizations.

EMERGENCY HOSPITAL OF THE SESQUICENTENNIAL EXPOSITION
Dr. A. Markley, interne; Miss Irene Parkins, nurse; Miss Leah Krumbine, nurse; Dr. H. R. Lefever, interne

Medical Aspects of the Sesquicentennial Exposition

Some two thousand acres of land are used in the Sesquicentennial Exhibition of Philadelphia. On this there are forty-five major exhibition buildings, two hundred and fifty pavilions, booths and stands, four flying fields, an attractive chain of lakes and lagoons and, many landscape gardens. The auditorium has a seating capacity of fifteen thousand and the stadium, where the heavyweight pugilists decided the championship, has a seating capacity of eighty-six thousand. The grounds are located at the junction of the Schuylkill and the Delaware rivers some ten miles south from the City of Philadelphia and adjoining the Navy Yard, which is used as a part of the exhibit.

The Philadelphia Department of Health has general supervision of all the sanitary arrangements of the grounds and has taken every precaution to safeguard the well being of the thousands of visitors who have been daily coming through the gates of the grounds. Food sold at the two hundred and fifty and more food concessions on the grounds, is inspected rigidly. Drinking water is furnished from the Philadelphia water mains and the grounds are sprinkled frequently to keep down dust.

The Philadelphia General Hospital has taken over an emergency hospital which was one of the first of the buildings completed. This is operated as an emergency branch under the general direction of Dr. Joseph C. Jones, Medical Director of the Philadelphia General Hospital. It is provided with an ambulance service and has treated one hundred cases a day since the opening of the exposition. Most of these cases are minor complaints and accidents. All serious cases are transferred to other hospitals after being given first aid. The hospital is provided with ten beds and the staff includes three internes and three nurses, an ambulance driver and motorman. All of these are drawn from the staff of the Philadelphia General Hospital, the interns being changed from time to time. The accompanying illustration shows this emergency hospital, the ambulance, the grounds and the hospital staff.

The walls of this, as of most of the other buildings on the grounds, are of stucco, of a pleasing gray color. The hospital, as is shown, is but one story high. On the left of the entrance is the office where complete records are kept of all patients who come under the care of the staff. A central hallway divides the men's ward from the women's. There are several separate rooms for grave cases. To the rear of the wards are a diet kitchen and rooms for the staff, which is generally changed fortnightly.

The hospital is directly across the street from the Palace of Education and Social Economy, Pattison avenue near Broad street, where the Philadelphia medical exhibit is housed. This is augmented by the displays of many nation wide medical organizations, in addition to those of the city proper, including the United States Public Health Service exhibit, in the Palace of the U. S. Government, mines, metallurgy and transportation and the State display on stabilizing the health of the public in the Pennsylvania Building.

The exhibit in the Palace of Education and Social

Aeroplane View of the Sesquicentennial Exposition

Economy was arranged by the committee on medicine and allied sciences which includes dentistry, pharmacy and nursing.

Dr. William Duffield Robinson heads the Executive Committee which includes also Dr. David Reisman, Dr. Henry D. Jump, Dr. E. R. Sausser, Dr. William A. Pearson, Dr. George H. Meeker, Dr. George A. Knowles and Dr. Seneca Egbert.

The chairmen named on the various committees were: Dr. John H. Jopson, surgery; Dr. C. C. Wolferth, medicine; Dr. Seneca Egbert, hygiene and sanitation; Dr. E. R. Sausser, dentistry; Dr. Charles H. LaWall, chemistry; Mr. Ambrose Hunsberger, pharmacy; Dr. Isadore Kauffman, tuberculosis; Dr. J. T. Rugh, orthopedic surgery; Dr. B. A. Thomas, urology; Dr. George Morrison Coates, laryngology; Dr. J. F. Schamberg, dermatology; Dr. D. J. McCarthy, neuropsychiatry; Dr. William N. Brad'ey, pediatrics; Dr. Willis F. Manges, radiology; Dr. Ross V. Patterson, medical education; Dr. Francis R. Packard, medical history; Dr. E. S. Barr, occupational therapy; Dr. J. D. McLean, public addresses; Dr. Moses Behrend, County Medical Society; Dr. T. B. Holloway and Dr. Louis Lehrfeld, ophthalmology; Dr. Hubley R. Owen, police department; Miss S. Lillian Clayton, nursing, and John M. Smith, hospitals.

The subdivisions of medicine at the display sponsored by Philadelphia show the prevention of infectious and contagious diseases, the prevention of heart and kidney diseases, cancer, etc. It has been the object to make this exhibit one easily understood by the average lay mind and to illustrate medical progress during the one hundred and fifty years since the Declaration of Independence which the Sesquicentennial International Exposition has been celebrating.

There is an excellent exhibit showing the whole story of the winning fight against tuberculosis and the modern methods of treating this disease which illustrates the value of heliotherapy.

The necessity for the reduction of the number of deaths from cardiac disease is emphasized by the State Society of Pennsylvania and the heart association is playing a prominent part in this battle with its display. Cancer prevention is illustrated graphically by the American Association for the Prevention of Cancer.

The medical division of the department of Public Safety of Philadelphia has another display which has attracted thousands of visitors. This is under the direction of the Chief Police Surgeon, Dr. Hubley R. Owen. How police and firemen are protected by modern methods in a great municipality is shown.

The bronchoscopic division is arranged under the supervision of Dr. Chevalier Jackson, the well known laryngologist. It portrays the rapid advances made in the work of removing foreign bodies from the air passages and instructs parents on the dangers of allowing dangerous objects to come within reach of the child at the time when every instinct leads it to place things in his mouth.

Handicraft by the physically incapacitated and mentally ill is shown in the occupational therapy division. The specimens are from different institutions in Philadelphia and vicinity. Adaptation of the work to the mental and physical ability of the patient is portrayed graphically.

There is much of interest to the pediatrist in the child health division. A feature is a replica of a city street in the slums with its many health problems strikingly depicted. This is contrasted with the model home, the best type of lying-in room and child hygiene lessons.

Entrance and Column of Original Thirteen States, Sesquicentennial Exposition

PUBLIC HEALTH AND MUNICIPAL HYGIENE

Much interest is displayed by visitors from all over the country in the divisions of immunology and bacteriology, public health administration and municipal hygiene, nutrition, domestic hygiene, industrial and social hygiene and entomology. Illuminated stage pictures show insects that purvey diseases, their development and breeding spots.

The Philadelphia County Medical Society, allied with the State Organization, shows how the public as well as the medical profession is benefited by cooperation among medical men. Membership in official medical organizations is shown with emphasis. More than five hundred square feet of space are used by the Interstate Dairy Council to show the handling and treatment of milk and its vital relation to the prevention of disease and to health.

Many sufferers from hay fever have visited the display on preventive measures against this prevalent disease. The various plants, shrubs and trees which produce this annoying ailment are shown and the public is informed regarding the prophylactic pollen injections that may be utilized. Samples of grass and weeds are shown under glass in the hay-fever booth with descriptions and parts of the city and United States where the growths are common.

DENTISTRY

Physicians, as well as dentists, are showing great interest in the display of the department of dentistry. A striking contrast is portrayed between a modern dental office and an old fashioned one. The place of the x ray is emphasized as an adjunct to modern dental work. Preventive dentistry and mouth hygiene in relation to children and public health are strongly emphasized.

Old fashioned surgical dental instruments are on exhibit beside those of the modern day. Artificial teeth of great antiquity may be seen carved from walrus tusks, porcelain and ivory.

PHARMACY

One of the most interesting portions of the display is the Pharmacy Department with features that go back a hundred years and longer. The spectator may view fixtures of the old Glentworth drug store, a type, seen often in Philadelphia more than a century ago. The owl—bird of wisdom—carved from a board and dingy with age, surveys the apothecary shop from its perch on an ancient stained shelf. Underneath is the Goddess Athena, used as a symbol for hundreds of years in European pharmacies. Bottles are shown that once held the strange concoctions of a superstitious day.

Some of the older relics viewed came from a day when Washington, Father of the Country, and other Colonial figures saw them in the quaint old pharmacy at Fifth and Chestnut streets.

The original iron mortar and pestle of this colonial apothecary shop can be seen with the date 1774 painted on the side. Powders ground in it at an early date in the history of American pharmaceutics still cling to the vessel.

There is a large "balance" with porcelain weights and pans resembling soup plates. On the floor is a large copper retort which nearly every visitor immediately classifies as a still.

There is a mortar and pestle dating back to the fifteenth century in Switzerland and another that was cast in 1689. Another bears a date of 1726 and still another, used by the Mexicans at an early date, is made of volcanic rock, while one carved from wood is of Aztec origin. Two oil portraits hang on the walls of former vice-presidents of the Philadelphia College of Pharmacy and Science. There also is a painting of Dr. George B. Wood, professor of chemistry at the institution from 1822 to 1831. Oil portraits are shown of Henry Troth, vice-president for eleven years and William Procter, Jr., professor of pharmacy, the "father of American pharmacy." Contrasted with these mementoes of bygone days is a modern pharmacy.

TUBERCULOSIS EXHIBIT

State sanatoria for tuberculosis patients are portrayed graphically by the State Department of Health under Secretary Miner. Heliotherapy's value is demonstrated forcefully. This exhibit is located in the Pennsylvania Building. Preventive measures are shown that are valuable in diphtheria with charts proving the cut in the death rate since the introduction of antitoxin and toxin-antitoxin in the prevention and treatment of this disease.

NURSING

At the Nursing Exhibit, in the Palace of Education, preliminary and professional training of the nurse is portrayed. The scope of her work is outlined and possibilities for specialization in this field is emphasized. A quotation from Herodotus surmounts the display; which epitomizes prophetically the work of the modern nurse.

The quotation says: "Neither snow, nor rain nor gloom of night stays these couriers from the swift completion of their appointed rounds."

In this booth a tactful trained nurse tells visitors and prospective pupils of the splendid service rendered humanity by this profession. On display are magazines from twenty-two different countries in thirteen different languages devoted to the nursing profession.

There is a duplication of Philadelphia's first infirmary in High street, Philadelphia's reproduction of Market street in the days of 1776 and before. In this reproduction of the Colonial thoroughfare are the homes of George Washington, Robert Morris, Thomas Jefferson and others of the founders. Benjamin Franklin's printing and book shop are shown, the counting house of Stephen Girard and the home of Dr. Shippen, a distinguished physician of Colonial days.

EXHIBIT OF THE GOVERNMENT

The Government's exhibit in the Transportation Building near the Navy Yard has been receiving high praise for many weeks past by medical as well as lay visitors. Many doctors who served in the World War have been among the visitors to the display of the United States Veterans' Bureau. On a large map is shown the locations of all the regional hospitals of the United States and there is an exhibit of furniture and other handicraft of incapacitated veterans.

"Public Health lies at the very foundation of all human welfare," is a message from Calvin Coolidge, President of the United States, displayed over the United States Public Health exhibit.

RECENT TYPHOID EPIDEMIC IN GERMANY

MABEL WEBSTER BROWN
New York

Germany has recently experienced what is reported to be the worst epidemic which she has suffered since the World War. This was the typhoid epidemic which seems to have had its origin in Hanover, Prussia, soon after the high floods suffered last summer by the central European countries. Thence it spread to Magdeburg, where thirty cases were reported on September 14; to Dinsburg, where there were a hundred cases on September 17; and to Halb-

FIG. 1.—Red Cross ambulances transporting the dozens of victims of the typhoid epidemic in Hanover, Germany. (*Henry Miller News Picture Service, Inc.*)

stadt and Groeningen, where there were sixty and thirty-five cases respectively by the middle of September. At the same time, the cases had increased in Hanover from six to eight hundred, with fourteen deaths on September 13th, to nearly fifteen hundred with fifty deaths by September 20th.

Almost immediately after the outbreak of the

FIG. 2.—River houses in which the typhoid epidemic of Hanover, Germany, is believed to have originated. (*Henry Miller News Picture Service, Inc.*)

scourge, the hospitals of Hanover were filled with sufferers and it became necessary to close all the schools and to convert many of them into temporary hospitals. Specialists on infectious diseases were hastily summoned from the universities of Frankfurt, Kiel and Göttingen, and scores of nurses were requisitioned from cities in the vicinity. By September 14th the cases in Hanover were reported as having increased to twelve hundred, with the result that many citizens became greatly alarmed and fled from the stricken city. As many as possible of those who remained were vaccinated free of charge at the various health stations.

Although the time since the start of the epidemic is so short, the health and medical authorities seem to agree that the probable cause of the epidemic was contamination of at least one of Hanover's three municipal reservoirs through the very high water caused by the recent floods in Germany and other central European countries. Hanover is situated on a small river, the Leine, a tributary of the Weser. It is a very old city and much of it is built on low ground, with many houses at the river's edge. Many of these, inhabited by the poorer and uneducated classes, had their lower stories under water during the period of the floods. Contamination of the city water supply was the unfortunate consequence. The illustration shows the type of old house, very picturesque but most unsanitary, on the river bank whence the trouble originated.

News Items.

Neurological Staff Conferences at Bellevue.—The Neurological Service at Bellevue Hospital will hold its staff conferences this year on the third Wednesday of each month. Dr. Foster Kennedy will preside.

New Course at New York University.—The School of Accounts, Commerce and Finance at New York University is offering a new course on hospital and institutional management. Dr. Edgar C. Hayhow, superintendent of New Rochelle Hospital, is in charge.

Memorial to Dr. Grossman.—Announcement has recently been made by the friends of the late Dr. Louis W. Grossman that they have decided to endow a suitable memorial in his name at the Beth David Hospital where he served for many years as a member of the obstetrical staff. A bronze tablet erected in the Memorial Hall of the hospital has been chosen to commemorate Dr. Grossman's life and work.

Dr. Bundesen Honored.—The Victor F. Lawson award for having "performed within the borders of Greater Chicago the most beautiful action or to have done the most beneficial thing for humanity," has been bestowed upon Dr. Herman N. Bundesen, Health Commissioner of Chicago. The award established in memory of its late publisher, Victor F. Lawson, was given by the *Chicago Daily News* in recognition of Dr. Bundesen's work for child health, and especially in the pure milk campaign which he inaugurated and carried through.

Yale Clinic for Infancy Research Enlarges Program.—Through a gift of the Laura Spelman Rockefeller Memorial, the Yale Psycho Clinic for Infancy Research has been enabled to extend its program of psychological investigation and its clinical service to young children. The staff of the clinic, directed by Dr. Arnold Gessell, has been increased by the appointment of several research associates, namely, Henry Marc Halverson, Ph.D., formerly head of the psychology department at the University of Maine; Dr. Marian Cabot Putnam, who has been serving as pediatrist and neurologist at the Boston Children's Hospital and as assistant in psychiatry at the Phipps Clinic; and Helen Thompson, Ph.D., formerly psychological research assistant at the Lincoln School, New York City. Emphasis is being laid at present by the clinic on cooperative research into the early stages of mental development, which will be concentrated on the first two years of infancy and bring into coordination data from different fields, including mental and physical measurements, language and motor capacity, habit and personality development.

New Health Organization for School Children.—The members of the medical and dental professions of the Astoria Center of Israel have organized a professional unit for the supervision of the health of the children in the center's schools.

Eye and Ear Hospital Sells Hospital Site.—The Manhattan Eye and Ear Hospital has sold the four story building at 351 West Thirty-fourth Street, New York, which has been for the past forty-five years conducted as the Metropolitan Nose and Throat Hospital by Dr. George B. Hope, to whom the property had been donated for hospital use. Upon Dr. Hope's death, the Manhattan Hospital took it over and are the present sellers.

New Milbank Health Centre.—The sum of $2,000,000 will be spent in the near future, according to an announcement by the Milbank Memorial Fund, on a new health centre for propaganda to be opened by the Fund at 325 East 38th Street, New York City. The building will be renovated and equipped to contain clinics for tuberculosis, social hygiene, and dental and child welfare, which will be maintained by the New York City Department of Health. The Community Health Council will make this its headquarters.

Medical University Extension Courses.—The Columbia University Extension and School of Medicine is this year giving courses in the diseases of children at the Babies' Hospital, Bellevue, and Willard Parker Hospital, in general medicine and dermatology, diseases of children, gynecology, surgery, pathology, neurology, ophthalmology, and surgical pathology at Mt. Sinai Hospital; a six weeks' course in physiotherapy for medical graduates at the Beekman Street Hospital; and a course in gastroenterology at Columbia University School of Medicine, 437 West 59th Street, New York City.

New Dormitory at Tuberculosis Preventorium.—A new dormitory at the Tuberculosis Preventorium for Children at Farmingdale, N. J., was recently opened with appropriate ceremonies and before a large gathering of notable guests, including many prominent physicians of New York, New Jersey and foreign countries. Among the speakers were Olga Nethersole, international representative at the recent Health Conference at Washington; Dr. Cepulic Vlad of Sagrad, Jugoslavia; Dr. Lydia Kemper of Berlin; Dr. A. F. Hulse of New York, formerly president of the Board of Directors of the Preventorium; and Dr. M. J. Fine of Newark. Among the European guests present were Dr. Reselin of Glasgow, and Dr. Stojanargitz of Jugoslavia.

Dinner to Academy Fellows.—Dr. Samuel A. Brown, the president of the New York Academy of Medicine and also the chairman of its committee on ceremonies in connection with the opening of its new building at Fifth Avenue and 103rd Street, has announced that the Academy will give a dinner in honor of the newly elected Honorary Fellows, at the Waldorf Astoria Hotel on Wednesday evening, November seventeenth. Dr. Brown stated that the selection of the Honorary Fellows was a matter of great importance to the Academy and that the twenty-two new Honorary Fellows had been selected on account of their high professional attainments and the contributions they had made to the progress of medical science during the last twenty years.

These new Honorary Fellows include the following doctors:

Robert Barany, Upsala, Sweden; Charles James Martin, London; Sir Charles Sherrington, Oxford; Marin T. Tuffier, Paris; Josef Jadassohn, Breslau; Friedrich Neufeld, Berlin; Carlos Chagas, Rio de Janeiro; Frank Billings, Chicago; George E. de Schweinitz, Philadelphia; John M. T. Finney, Baltimore; Theobald Smith, Princeton; Edward William Archibald, Montreal; Sir George Newman, London; Henry Head, London; George F. I. Widal, Paris; Friedrich Müller, Munich; Vittorio Putti, Bologna; John Jacob Abel, Baltimore; Harvey W. Cushing, Brookline; George Dock, Pasadena; Chevalier Jackson, Philadelphia; William Sidney Thayer, Baltimore.

Dr. Brown also stated that invitations would shortly be issued for the opening exercises which will be held at the new building on Thursday, November eighteenth, at three-thirty. At that time an invocation will be given by Rev. Henry Sloane Coffin, D.D., and brief addresses by the president of the Academy and the chairman of the building committee, Dr. Arthur B. Duel. In addition to the Fellows of the Academy several thousand guests will be invited to these ceremonies.

Opening of the Johns Hopkins School of Hygiene and Public Health.—The semicentennial celebration of Johns Hopkins University opened on October 22 with the dedication of the new building for the School of Hygiene and Public Health, made possible by the Rockefeller Foundation. The school cost more than one million dollars, and is the first institution of its kind in the world. It is located near the Medical School, the nurses' school, and the new dormitory for nurses, which was opened the day before. The new School of Hygiene and Public Health contains the most complete laboratory in the world for research in and teaching of hygiene. Two rooms are devoted to equipment for producing any type of climate desired.

Personal.—Dr. Alexis Carrel and Dr. L. de Nuoy, of the Rockefeller Institute, have returned to New York after spending the summer at their estates in France.

Dr. Bernard W. Carey, director of the Child Health Demonstration at Athens, Ga., has been given the honorary degree of Doctor of Public Health by the University of Georgia in recognition of his services with the demonstration. The Athens demonstration is one of those being financed by the Commonwealth Fund of New York City.

Dr. Alfred Adler of Vienna will arrive in the United States in the near future to give lecture courses in several of the larger cities of the country.

Dr. Ellis I. Smith, for the past two years senior resident physician at the Essex County Isolation Hospital, Belleville, has been appointed superintendent of that institution. Dr. Smith is twenty-eight years of age and the youngest hospital superintendent in the country. He was born in Texas.

Another young physician from the South, Dr. Vincent Archer of Black Mountain, N. C., also twenty-eight years of age, has been appointed professor of Röntgenology in the Medical School of the University of Virginia.

Among prominent physicians from foreign lands who visited the New York Academy of Medicine during October were Dr. L. O. Zeno of Buenos Aires, Dr. A. A. Busch of London, Dr. Jose Izguierd, professor of anatomy at the University of Caracas, Venezuela; Dr. Harry G. Dorman of Beirut, Syria; Dr. Georges Loewy of Paris, and Dr. M. Mayeda of Osaka, Japan. Other prominent visitors were Dr. E. D. Fenner and Dr. D. O. Joachim of New Orleans, Lt. Col. Fred A. Haggard, of the Medical Reserve Corps, Ft. Worth, Texas; Dr. Hugh Davison of the Episcopal Hospital, Philadelphia, and Dr. H. C. Pedersen, of Fremont, Nebraska.

Gifts and Bequests.—The will of the late Mrs. Harkness provided cash legacies of $36,650,000 to charities and institutions of public welfare, among which were twenty million dollars to the Commonwealth Fund; one million, five hundred thousand dollars to the Presbyterian Hospital of New York City; three million dollars to Yale University; one million dollars to the American Museum of Natural History, and one million dollars to the New York Zoological Society. Among bequests that have been exceeded are those to the Commonwealth Fund, which has received $22,302,263, and Yale, which has received $25,000 more than the three million dollars. Among the gifts made by Mrs. Harkness between the time of the execution of her will and her death were the following: the gift to the Commonwealth Fund mentioned above; to the Presbyterian Hospital in the City of New York, $1,801,600, and to the Flower Hospital, New York Homeopathic Medical College, one hundred thousand dollars.

Society News and Notes.

At the twenty-seventh annual meeting of the New York State Conference of Charities and Correction, to be held at the Hotel Statler, Buffalo, November 16-19, public health in relation to the conference program will be discussed. The public session has been scheduled for the afternoon of Friday, November 19. The topics which will be discussed are: New Outlooks in Public Health, How Far Can Communicable Diseases Be Put Out of Business? Discussion and Demonstration of Administration of Toxin Antitoxin, and Twentieth vs. Eighteenth Century Health Methods.

* * *

The Harmon Foundation, with headquarters at 140 Nassau Street, New York City, supported by the American Red Cross, the Yale School of Nursing, the American

Nurses' Association, the Bureau of Nursing Education, the Henry Street Settlement, and a large number of similar organizations, is making a study of plans for pensioning nurses. The details have not as yet been made public, but a proposal has been made that nurses, during their periods of employment, pay one dollar a week, and that private patients be taxed a two dollar a week surcharge, and that this will provide a fund sufficient to give the nurses who subscribe to the plan a retirement annuity amounting to fourteen hundred yearly at the end of thirty years.

* * *

The New York Tuberculosis and Health Committee has recently completed an intensive study of 1,078 newsboys. The examinations showed that the percentage of physical impairments did not seem to be any higher than among boys not engaged in street trading. The outdoor life seems to balance the strain of long hours, the loads carried, and the nervous tension of the occupation. About two thirds of the boys examined were found to be backward in their school studies, but the investigators attributed this to the long and unusual hours of work rather than to mental or physical disability.

* * *

Announcement has been made of the official disbanding of the Section of Psychiatric Social Work of the American Association of Hospital Social Workers at its fourth annual meeting at Cleveland last May. A new and independent organization has been established to be known as the American Association of Psychiatric Social Workers. The withdrawal from the parent organization was decided upon after a careful consideration of the development during recent years of psychiatric social work, which has been outside the hospital phase of the work and more closely allied to general social activities. The following were elected officers of the new American Association of Psychiatric Social Workers: president, Mrs. Maida H. Solomon, of the Boston Psychopathic Hospital; vice president, June Lyday, of the Iowa Psychopathic Hospital at Iowa City; secretary treasurer, Kathleen Ormsby, of the National Committee for Mental Hygiene, New York City; members of the Executive Committee, Sarah Ivins of the Bureau of Children's Guidance, New York City; Mary C. Jarrett, Boston; Grace F. Marcus, National Committee for Mental Hygiene; Katherine Moore, Michael Reese Dispensary, Chicago; Helen L. Myrick, Illinois Society for Mental Hygiene, Chicago; and Mildred Scoville, Commonwealth Fund, New York city.

The American Medical Association of Budapest, Hungary, which was organized for the promotion of international post-graduate study, has issued a statement defining the nonmedical indications of artificial abortion. These are given as the social, the eugenic, and rape. The conclusions summarized are: Induction of abortion to save life or to prevent grave illness is a recognized remedy; Induction of abortion for nonmedical indications is prohibited by law, and should not be recognized by the profession, except in cases when extreme poverty may aggravate an otherwise improvable medical condition; Our knowledge of heredity is entirely too limited at the present time to permit us to seriously consider the eugenic indication; In rape we are confronted by a legal and social problem which we have no moral right to solve by the destruction of a potential human being.

Among meetings of societies to be held during November are the following: American Association of Railway Surgeons, Chicago, November 3-5; the Section of Biology of the New York Academy of Sciences, American Museum of Natural History, November 8; Southern Medical Association, Atlanta, November 15-18; the New York Microscopical Society, American Museum of Natural History, November 19; the Section of Anthropology and Psychology of the New York Academy of Sciences, American Museum of Natural History, November 22; the New York State Stomatological Medical Society, New York city, November 23.

* * *

Meetings at the Academy of Medicine early in November will include the following: stated meeting of the Academy, November 4, the papers of the evening to be by Dr. John M. Finney of Baltimore and Dr. Herbert S. Carter; a combined meeting of the Section of Genito-Urinary Surgery and the New York Society of the American Urological Association, November 3, with presentation of new instruments by Dr. S. R. Woodruff, and papers by Dr. William H. Meyer and Dr. Eugen Joseph of Berlin; the Section of Neurology and Psychiatry, November 9, with presentation of cases by Dr. E. D. Friedman, memorial address for Dr. Charles Bates Dunlap by Dr. George H. Kirby, and papers by Dr. I. S. Wechsler and Prof. August Wimmer, of the University of Copenhagen; the Section of Pediatrics, November 11, with papers by Dr. S. Adolphus Knopf and Dr. Charles Hendee Smith; the Section of Otology, November 12, with presentation of cases by Dr. Jay D. Whitham, and papers by Dr. Joseph H. Globus and Dr. Walter E. Dandy of Baltimore.

The New York Academy of Sciences has announced that the A. Cressy Morrison Prize, offered for the best thesis on the subject, What may be proved from our present knowledge as to the possibility or impossibility of released intra-atomic energy constituting an important source of solar and stellar energy? will be awarded in December of this year. The prize, which was at the time of announcement last May, limited to members of the Academy, is now announced as open to all. There are no change in conditions, except that the award has been increased to $250.

* * *

The Bureau of Courses of the Medical Faculty of the University of Vienna has announced a series of special annual courses in German to enable physicians to continue or complete their studies, or to avail themselves of the opportunity for training in specialties. Four times each year —in February, June, September and November—international Fortbildungskurse (finishing courses), each lasting two weeks, are given for those who wish to specialize in the branches of medicine. Information about these courses may be obtained by writing to the Kursbureau, Vienna Faculty of Medicine, Wien VIII, Schlösselgasse 22, for the first series; and to Dr. Kronfeld, Wien IX, Porzellangasse 22, for the second series.

* * *

The Committee on Medical Education of the New York Academy of Medicine has prepared a useful synopsis of approved opportunities offered in Greater New York for graduate study in Roentgenology. These are in brief: six courses at the New York Postgraduate Medical School and Hospital; a postgraduate course for physicians only at the New York Hospital to be given by Dr. Webster W. Belden and Dr. John Remer; a special course for medical graduates at New York University and Bellevue Hospital Medical College; and an advanced course at the New York Eye and Ear Infirmary covering the Röntgenology of the head and accessory sinuses, and the localization of foreign bodies in the eye. A list is given also of the hospitals in Greater New York offering special interneships and externeships in Röntgenology.

* * *

The ceremonies in connection with the opening of the new building of the New York Academy of Medicine, corner of Fifth Avenue and 103d Street, will include the following events: a dinner in honor of the new Honorary Fellows at the Waldorf-Astoria, Wednesday, November 17, at 7 P.M., addresses will be delivered by Dr. Samuel A. Brown, president of the Academy and by several of the Honorary Fellows; the opening exercises at the new building will be held on Thursday, November 18, at 3:30 P.M.; the invocation will be delivered by Rev. Henry Sloane Coffin, D.D.; Dr. Brown will make an address on The Academy —Its Services in Medical Progress, and Dr. Arthur B. Duel, chairman of the Building Committee, will speak on the Building of the Academy. The Fellows and their friends are invited to attend a reception and inspection of the new building to be held on November 18 from four till six o'clock. The first meeting to be held in the new building will be a stated meeting of the Academy in Hosack Hall, Fifth Avenue and 103d Street, Thursday, November 18, at 8:30 P.M. At this meeting there will be an election of Honorary Fellows and the Carpenter Lecture will be delivered by Dr. Michael I. Pupin of Columbia University; his subject will be Ionization and Chemical reactions. The administrative offices of the Academy will be transferred to the new building on November 8.

Book Reviews

THE BIPOLAR THEORY

A Bipolar Theory of Living Processes. By George W. Crile. New York: The Macmillan Company, 1926. Pp. 405.

This work may to many appear impractical and somewhat theoretical yet it seems to contain a more basic approach to protoplasmic life and activity than has so far been generally accepted. Here and there indications of Crile's summation have been manifested as is indicated in his bibliography, but an integration such as Crile attempts has not been presented. Crile would find much support from the modern school of psychopathology which finds symbolical manifestations of what he demonstrates in the laboratory. This being the case there must be validity behind his findings for the symbol is an integrated index to function—to life itself. The work of Ellice Macdonald, of Philadelphia, which has been published in this JOURNAL, tends to confirm all that Crile postulates. Perhaps a bit ahead of his time but tending to a basic foundation.

ALBUMINURIA

On the Relation between Albuminuria and Hydrogen Ion Concentration of the Blood and Urine. Inaugural Dissertation by Alfred Bjure. Upsala: Almquist & Wiksells 1925.

An excellent monograph in which the pathogenesis of orthostatic albuminuria, the albuminuria of exercise and the albuminuria of diabetes, is discussed. The investigation is clinical, the subjects of the study are patients under control on the medical service of the University Hospital at Upsala.

The monograph contains a critical analysis of the pertinent literature and a good bibliography. It represents a vast amount of work and is undoubtedly a noteworthy contribution to the subject.

CLINICS

Medical Clinics of North America. Philadelphia Number, Volume 10, Number 2. September, 1926. Philadelphia and London: W. B. Saunders Company, 1926.

The contribution by David Reisman is Diagnosis and Treatment of Acute and Chronic Myocardial Weakness, with special emphasis on chronic failure of circulation. The clinic of Joseph Sailer and Frank B. Lynch is on Backache in Blood Stream Infection, and includes five cases that present certain common features of a special type of backache although the actual pathology may vary. John H. Stokes discusses the differential diagnosis of psoriasis and syphilis, the treatment of lupus vulgaris, with special reference to the misuse of x ray and radium, the diagnosis of disseminate erythematous lupus, and the problem of malignancy in the presence of syphilis. Russell S. Boles presents a case of extraordinary dilatation of the stomach secondary to malignant obstruction of the pylorus with remarks on the early diagnosis of cancer of the stomach; also a case of Hodgkin's disease with primary involvement of the retroperitoneal glands. William D. Stroud offers a preliminary report on auricular fibrillation to show that there is a definite place for quinidine sulphate in the treatment of such patients. John C. Gittings presents malnutrition as the modern pediatric problem. Nondiabetic glycosuria is discussed by Leon Jonas. Burgess Gordon discusses the heart in tuberculosis. Henry LeRoy Bockus and Harry Shay discuss the subject of obstructive jaundice and present some interesting cases. Thomas Klein and Harold R. Keller discuss the treatment of chronic arthritis, especially with Coley's fluid. F. C. Knowles and John B. Ludy present some cases of pellagra. Martin E. Rehfuss shows interesting cases of organic duodenal pathology. William Egbert Robinson reviews the value of pain and certain reflex phenomena in diagnosis.

Medical Clinics of North America. Chicago Number. Volume 9, Number 5. Philadelphia: W. B. Saunders Co., 1926.

This number represents contributions from the Chicago members of the medical profession. As usual, the clinical side of various branches of medicine is stressed. The cases presented are thoroughly prepared, clearly stated and discussed from a didactic point of view. The important features are that, while the matter presented is of common interest to the profession, dealing with cardiovascular, gastrointestinal, neurological, blood and metabolic diseases, etc., the cases employed to illustrate the conditions in question frequently embody unusual features. Points which ordinarily may lead to confusion are elucidated, and methods for differentiation and classification of the cases dealt with exposed. The value of these volumes lies not only in the character of the cases presented, but also in the methods used in working them up, both of which should prove of great help to the busy general practitioner.

DIETETICS

Practical Dietetics for Adults and Children in Health and Disease. By Sanford Blum, A.B., M.S., M.D. Second Revised Edition. Philadelphia: F. A. Davis Co., 1926.

The second edition of this useful book is very welcome. The arrangement is by disease in alphabetical order. The presentation is direct, clear, and interesting. Under each head, a type patient is considered, a type dietary outlined, and this is then followed by the more usual lists of foods allowed and prohibited, grouped in classes.

It is suggested that future editions include diets for the various cancers of the alimentary canal and for ulcerative colitis.

X RAY EXAMINATION OF GASTROINTESTINAL TRACT

La Radiologie in médecin praticien. Radiodiagnostic des maladies de l'appareil digestif. Par R. Ledoux-Lebard. Paris: Masson et Cie, 1925.

Ledoux-Lebard gives a concise and practical description of all the methods used in x ray examinations of the gastrointestinal tract and also a detailed account of a correct interpretation of the pictures obtained.

The practitioner will also find in this useful book the indications for the use of the x ray photographs and fluoroscopy.

PROCTOLOGY

A Manual of Proctology. By T. Chittenden, Ph.B., M.D., F.A.C.S. Second Edition, Thoroughly Revised. With 101 engravings. Philadelphia and New York: Lea & Febiger, 1926. Pp. 294.

This manual, now in its second edition, is a useful publication. Crowded into less than three hundred pages are the rich fruits of much practical experience. This is presented in such a way that not only the general practitioner, but even the surgeon should have frequent occasion to refer to this volume. The style and arrangement are particularly fitted for ready reference.

It is especially to the man in general practice that the work must make its greatest appeal. Such common and important topics as the catarrhal diseases of the rectum and colon, ulcerative colitis, anal fissure, hemorrhoids, pruritus, and cancer are very adequately presented. In all cases, the palliative, as well as the radical treatment is described in detail.

The concluding chapter of this book, now in the second edition, is on radical operation for cancer of the rectum. It is written by Dr. R. C. Coffey, of Portland, Oregon.

FIBROUS OSTEODYSTROPHY

Pathologisch-Anatomische Studien Uber Die Osteodystrophia Fibrosa (Sog. Ostitis Fibrosa v. Recklinghausen). Akademische Abhandlung zur Erlangung der medizinischen Doktorwürde mit Genehmigung der weiterfahrenen Fakultät zu Upsala. Vorgelegt von Ture Stenholm, Med. Lic., Fil. Mag., Norrl. Aus dem Pathologischen Institut des Städtischen Krankenhauses im Friedrichshain zu Berlin. (Abt-Direktor: Prof. Dr. L. Pick.) Upsala: Almquist & Wiksells Boktryckeri-A.-B., 1924. Pp. vi-211.

This monograph was presented as a graduation thesis for the medical degree. Under the direction of L. Pick twelve cases of this disease were carefully studied. Heretofore, only the gross anatomy of the macerated bones were studied and attention was paid almost exclusively to the histology of the disease, with the result that an incorrect conception of the disease prevailed. The author devoted himself to a combined study of both elements. He also studied not only the bones affected but also all the other bones of the body, which is necessary in order to gain a correct insight into the extent of the pathological changes and the development of the disease. In this way the different stages of the disease are met and studied. The very early stages of the disease can be studied only in bones that are macroscopically still intact. Such a study requires investigation not only of the fresh necropsy material (bones) but also of the wet preserved and macerated specimens. In addition, the endocrine glands were also investigated. Twelve cases were studied clinically and pathologically.

The following conclusions are drawn:

1. The term "ostitis" is incorrect as there is no anatomical or histological evidence of a chronic inflammation.

2. The disease is produced by nutritional disturbances of the bone and shows the character of a degenerative reparative process. Hence the term "fibrous osteodystrophy" is more appropriate.

3. The same condition may apparently be produced by originally different factors, but they all have the fundamental nature of a nutritional disturbance.

4. Fibrous osteodystrophy is an independent entity which must be sharply differentiated from true osteomalacia and rachitis.

5. The histological picture of this disease may also be seen in circumscribed areas in other diseases, occasionally in osteomalacia, severe rachitis, Möller-Barlow disease, in the vicinity of chronic osteomyelitides or malignant bone tumors, and in bone echinococcus, which diseases also show a reaction to nutritional disturbances of bone—a specific sign.

6. The lacunar resorption here also is the only form of destruction. Therefore all the osteoid ridges of bone are new formations of bone substance, which is the result of regular osteoblastic activity and, occasionally, of direct metaplasia.

7. The associated tumors in certain cases are neither inflammatory products nor blastomas and they indicate the end stage of the resorptive process.

8. Fibrous osteodystrophy is up to the present time the only demonstrable basis for the development of bone cysts. These usually are situated in the brown tumors, but also occur occasionally in areas free of tumors.

9. The cysts apparently originate in dilated veins and lymph vessels.

10. The variations in the forms of this disease are determined by the following factors: a, skeletal involvement—generalized, single, or transitional forms; b, involvement of single bones—total or partial; c, localization in bones—cortical or endosteal or medullary; d, change in volume of the bone—hyperostotic or hypostotic; e, quality of the resulting bone tissue—porotic or sclerotic; f, associated symptoms—absence or presence of tumors or cysts; g, age incidence—infantile, juvenile, adult, or senile.

11. The existence of the monostotic form was first described by the author.

12. The medullary form was associated with cysts in one case.

13. The senile porotic generalized form is the same as the socalled Paget's disease of bone, and is associated with marked arteriosclerotic changes in the arteries of the bone marrow and the nutrient arteries with the resulting nutritional and functional disturbances of fibrous osteodystrophy.

14. In the hypostotic form there is craniotabes, as in rachitis.

15. The partial involvement of a bone may (without the presence of brown tumors or cysts) closely resemble the x ray picture of a neoplasm.

16. Some of the cases of socalled leontiasis ossea belong to this group of fibrous osteodystrophy; in others some other genesis is undoubtedly responsible.

17. The parathyroid tumors observed in fibrous osteodystrophy are not blastomas, but are purely benign parenchymatous hyperplasias, secondary to the bony involvement and the result of the demand for increased function.

18. Positive parathyroid involvement is observed almost regularly in cases with brown tumors and cysts, which represent the final stage of the changes in this disease.

19. In general, there is a parallelism between parathyroid enlargement and the disturbance of calcium metabolism. But the intensity of this disturbance is measured not only by the intensity of the bony changes, but also by the duration of its course.

Medicoliterary Notes.

Interesting features of the October issue of the *American Journal of Public Health* are the initial article, The International Sanitary Conference, by Surgeon General Hugh S. Cumming; an editorial paying tribute to the life and work of Dr. Victor C. Vaughan, who celebrated his seventy-fifth birthday on October 27th; and a supplement giving in detail the requirements for public health degrees in the United States and Canada.

* * *

The first issue (October) has appeared of a new periodical bearing the title *Children, the Magazine for Parents.* This number contains articles entitled: Parents, We Are Here! by the editors; A Magazine for Parents, by George J. Hecht; The Stuff Contentment Is Made Of, by Dorothy Canfield Fisher; Before Your Child Goes to School, by Helen T. Woolley, Ph.D.; Inside Tips for Fathers, by Ernest R. Groves, Ph.D.; The Thompson Twins Talk Things Over; Do You Know Your Child's Teacher? by Robert E. Simon; A Mother to Ten Thousand, by Marion Brockway; Salesmanship for Parents, by Harry Goldsmith; Janet Kept Her Vow, by Carolyn Hosmer Rhone; Checkening, by Irma Morris; Two's Company; What's Three? by Clara S. Littledale; Shall Jack Play Football? by Arthur R. Forbush, and Fruit Juices and Child Health, by Dr. Alfred F. Hess. The magazine is published by the Parents' Publishing Association, Inc., 353 Fourth Avenue, New York City. Its purpose is stated as that of assisting parents to bring up their children by setting before them the results of investigations made by physicians, psychologists, educators and other authorities.

* * *

Public Health Reports for October 1st is devoted chiefly to a description with illustrations of an experimental water purification plant constructed and now being operated by the U. S. Public Health Service on the grounds of the laboratory of stream pollution investigations at Cincinnati, by Frederick J. Moss, assistant sanitary engineer of the Service; followed by a preliminary review of the results of primary experiments in the same line, by H. W. Streeter, also sanitary engineer of the Service.

* * *

The course of eighteen lectures now being given at the New School for Social Research, New York City, by Dr. S. Ferenczi of Budapest, and which will continue until February 15, 1927, will include discussion of the topics of suggestion and psychoanalysis, the development of the ego and the instincts, the ego and the personality, the Freudian metapsychology, the technic of psychoanalysis, the chief forms of neurosis and psychosis, and character and its possible alterations through psychoanalysis.

* * *

Methods and Problems of Medical Education, Fifth Series, published by the Division of Medical Education, of the Rockefeller Foundation, includes descriptions, excellently illustrated of the various departments pertaining to medicine and related subjects of the Washington University School of Medicine at St. Louis, Missouri; the department of physiology of the University of Pennsylvania; the department of physiology of Peking Union Medical College; the various similar departments of McGill University, Montreal; the out patients' department of the Royal Victoria Hospital at Montreal; the mental prophylaxis service of the Department of the Seine, Paris; the laboratory and dispensary building of the Presbyterian Hospital of Philadelphia; the modern mission hospital in Soochow, China; the regional centre for combatting cancer at Toulouse, France; the charting of clinical records at Mt. Sinai Hospital, New York City; the surgical didactiscope and asciatic lamp at Montpellier University, France; the Institute of Pathology at the University of Utrecht, Netherlands; and the Students' Unit Medical Laboratory at the University of Wisconsin.

Nine rattlesnakes and a large number of moccasins at the Bronx Zoo recently did their bit for the cause of medicine by contributing in a single day enough venom to kill—or cure—a score of people. The importation of antisnake serum from Brazil is forbidden by a regulation of the U. S. Public Health Service, so Dr. Afranio da Amaral, one of Brazil's foremost experts, now working at the laboratories of the Mulford Company at Glenolden, Pa., Dr. Thomas Barbour of Harvard University, and the United Fruit Company are cooperating to produce a supply for America. Dr. Raymond L. Dittmars, curator of reptiles at the zoo, is reported as having stated that in about four months there will be a sufficient supply in this country to meet all emergencies. A simple apparatus for extracting the poison had been prepared, according to an account in the *New York Times,* consisting of a rubber diaphragm stretched across the top of a small vial, the whole having been screwed to a table. The snakes were brought into the room in heavy ashcans and encouraged to plunge their fangs into the rubber, thus discharging the venom into the vial.

* * *

Chicago's Health for October, 1926, the weekly bulletin issued by that city's Health Department, is devoted to a description of the relief measures organized and carried out by Chicago for the sufferers in the Florida hurricane, especially through the *Chicago Herald Examiner's* Illinois Central Relief Train.

* * *

Crime and the Alarmists is the title of an interesting article in *Harper's Magazine* for October by Clarence S. Darrow.

* * *

The continent of Australia has been divided into circular districts each with a radius of two hundred miles to be covered by flying doctors. In this way a physician in government employ may be summoned to any place in the whole country where he may be needed and reach there in a comparatively short time.

* * *

Dr. C. Ward Crampton, director of the Health Service Clinic of the Post Graduate Medical School and Hospital of New York City, has contributed to the *Nation's Health* for August an interesting account of "the friendly clinic" as a help to the cause of health examinations as illustrated by the work of the Health Service Clinic, which was established as late as January of 1925. Another significant article in the same issue is entitled the Clean and Safe Milk Campaign to Stimulate Use, by Dr. S. J. Crumbine, general executive of the American Child Health Association, New York City.

* * *

One of the largest firms of pearl dealers in Japan has had built in the Grand Imperial Shrine of Isé a miniature pagoda, in which more than ten thousand pearls are used. This monument was publicly dedicated recently to the "souls" of pearl oysters, which, according to a firm belief of the Japanese, must be propitiated whenever they are robbed of their pearls.

* * *

Dr. Charles V. Chapin, superintendent of health of Providence, has been recently quoted as declaring that the motor car is causing the extinction of the common house fly, according to the *Science News Letter.* "Each year, as the automobiles have increased in number," Dr. Chapin states, "the flies have diminished. . . . The reason lies in the fact that the auto has done away with the demand for horses. This being so, there are fewer stables today than ever before. Naturally this has resulted in a decrease of manure piles, which have been the principal breeding places of flies."

* * *

The Upper Mississippi River Wild Life and Fish Refuge is in process of being established as soon as the land for it has been acquired. This is the chief American airway for migratory birds, so well located to serve as a feeding ground and resting place, and as a natural retreat for animals. The water abounds in many kinds of fish and mussels which will also be protected. The Biological Survey and the Bureau of Fisheries will be the guardians of the huge estate, which will extend from Rock Island along both sides of the river almost continuously through Illinois, Iowa, and Wisconsin to Minnesota, a distance of 300 miles.

A recent important publication of interest to physicians is *A Popular Encyclopedia of Health,* by Lee K. Frankel and Donald B. Armstrong, published by Albert and Charles Boni, New York.

Abstracts from Current Literature

NEUROPSYCHIATRY

Meningioma of Intracranial Sinuses.—E. B. Towne (*Annals of Surgery,* 83:3) states that meningiomas, or dural endotheliomas, are encapsulated tumors which do not invade the cortex, but which frequently invade the dura and the overlying cranial bone. They arise from nests of arachnoid cells which often lie on the arachnoid villi, which project into the intracranial venous sinuses. Theoretically, meningiomas might invade the venous sinuses of the dura. Only one example of invasion, without occlusion of the sinus, has been found in the literature. Two additional cases are reported. In one, the superior longitudinal sinus was occluded. In the second, a meningioma had invaded the inferior longitudinal sinus and grown extensively in the venous system, terminating in the superior vena cava. The tumor had secondarily invaded and broken through the venous walls in many places.

Such invasion of the venous system may convert a meningioma, which is otherwise favorable for surgical treatment, into an irremovable tumor. The surgeon should examine the adjacent venous sinus for possible involvement when the tumor is attached to the dura. Necropsy in the second case suggested that an early intravenous extension, before secondary invasion of the wall of the vein, might be successfully excised.

Staphylococcus Meningitis.—T. S. Moise (*Surgery, Gynecology and Obstetrics,* 42:3) asserts that the sacrolumbar region is a common site for developmental anomalies among which are included the above mentioned congenital dimples, sinuses, cysts, and tumors. These cases rarely present a connection between the spinal canal and the skin surface.

Other congenital lesions occurring in this region are instances of spina bifida, with all gradations from an unnoticed spina bifida occulta with no external evidence of a defect to a fusion of the spinal cord with the integument. The cases showing a connection between the spinal canal and the exterior do not as a rule survive infancy. The author reports a case which showed a congenital sacral sinus with an underlying spina bifida and a direct connection between the skin and the spinal canal. The occurrence of a pilonidal sinus with an underlying spina bifida and an irregularity in the fusion of the sacral vertebræ furnished additional evidence in favor of the view that such sinuses are developmental anomalies resulting from a failure of the medullary canal to become completely obliterated. This lesion had given the patient no cause for worry until the eighteenth year of his life when it served as the portal of entry for a meningeal infection. A sacral laminectomy with drainage was performed with subsequent recovery from the meningitis.

Traumatic Neuritis of Ulnar Nerve.—H. Platt (*British Journal of Surgery,* 13:1) divides ulnar nerve lesions into three main groups and outlines his points of emphasis for each group as follows:

1. Ulnar nerve lesions associated with recent fractures of the lower end of the humerus.

Involvement of the ulnar nerve is a rare complication in recent fractures of the lower end of the humerus. The common type of fracture to be accompanied by a lesion of this nerve is separation of the internal condyle. The nerve lesion is usually a primary contusion—a physiological block without loss of continuity. The symptoms are slight, and rapid spontaneous recovery tends to occur. In exceptional cases the primary neuritis may increase in severity during the early stages of treatment, and the lesion may pass etilogically into the secondary class. A secondary ulnar neuritis of this type may be an unavoidable sequela. In such cases a friction or tension neuritis is produced as a result of a disturbance of the normal relation between the nerve and its bed. A secondary neuritis may also be induced by injudicious treatment, i.e., the use of forced passive movements of the elbow in the first few weeks after the injury. Under similar circumstances a secondary neurities may arise de novo. In all cases of severe and persistent neuritis the nerve trunk should be explored and displaced to a new bed in front of the internal condyle.

2. Late ulnar nerve involvement after certain fractures.

Late involvement of the ulnar nerve (delayed ulnar palsy) is a characteristic remote sequela of certain fractures of the external condyle sustained in early childhood. The clinical picture embraces three phases; a, The fracture in early life; b, The latent period—this is rarely less than ten years; c, The development of neuritis. The neuritis is a friction or tension lesion. It is predetermined by the existence of a gross cubitus valgus deformity. The nerve trunk is compelled to take a longer course, and becomes stretched like a bowstring in the shallow postcondylar groove. The onset of symptoms is often associated with a period of strenuous use of the limb in which repeated flexion movements of the elbows are carried out. Operative treatment is indicated in all cases. It is necessary to relieve the nerve from friction, and to shorten its course. Two procedures are worthy of adoption, namely, anterior transposition of the nerve, and supracondylar osteotomy.

3. Recurring dislocation of the ulnar nerve.

There are special types of ulnar nerve injury which are primarily determined by an alteration in the normal relation between the nerve trunk and its bed in the postcondylar groove. Under such conditions the nerve becomes exposed to the cumulative trauma of repeated over-stretching or friction. The nerve lesions produced in this way are ordinarily of the incomplete type, and may be described under the broad title of traumatic neuritis. Three clinical groups may be distinguished: Ulnar nerve injuries associated with recent fractures of the lower end of the humerus. In these spontaneous recovery is the rule; operation is called for in rare cases of severe and persistent neuritis. Late ulnar nerve involvement after fractures. Recurring dislocation of the ulnar nerve. In the two latter groups operative treatment is indicated as a routine. There is one simple and effective operation which is universally applicable in all cases of traumatic neuritis of the ulnar nerve in the postcondylar groove, viz., anterior displacement of the nerve trunk.

Median Nerve Lesions.—D. Crile (*Surgery, Gynecology and Obstetrics,* 42:3) has observed that in fractures of the arm in which the median nerve is involved certain color phenomena may be produced by constricting the arm at diastolic pressure. These color or vasomotor phenomena correspond precisely to the anesthetic area and gradually diminish both in intensity and extent as sensation returns.

The author says that the value of this sign seems to be in its objective qualities. It is a sign which cannot be feigned and as such is of great value in differentiating the malingerer from the unfortunate. It presents the means of delineating in a graphic manner cutaneous areas the nerve supply of which is blocked. It supplements the tactile tests and should be a useful means of studying the physiology and pharmacology of vasomotor control. Its value lies in the facility with which it may be produced in recent cases contrasted with the length of time required to produce visible vasomotor disturbances as they appear in chronic cases. The appearance of this sign in two cases does not, of course, establish it as a constant or unvarying sign of peripheral nerve lesions, and therefore the absence of this sign is of no importance. However, the presence of this sign establishes objective evidence of a nerve lesion.

Nerves of the Stomach.—E. D'Arcy McCrea (*British Journal of Surgery,* 13:52) puts forth evidence to show the following:

That the anatomical distribution of the nerves to the stomach is sufficient to account for instances of reflex spasm or of incontinence of the pylorus in the case of gastric or duodenal ulcer, and of spasm or of atony of the body of the stomach with duodenal ulcer. That the "ulcer bearing" area of the stomach correspondens to the area in which the nerve branches are chiefly grouped. That local spasm with resultant anemia is a probable cause of the chronicity of ulcer, aided by factors such as retention and infection set up by reflex spasm. That certain of the "gastric neuroses" may be exactly simulated by the resection of either the vagi or the splanchnic nerves. That the results of nerve stimulation and therefore of nerve irritation can also simulate certain of these "neuroses". That the phenomena grouped under the title of the nervous dyspepsias or gastric neuroses

may have at least three sources of origin; and that certain of these conditions will probably come to be regarded as preulcerous. These sources are: Peripheral irritation of the nerves, manifested by gastric signs and symptoms, lesions of the nerve paths, and central disorders, possibly of endocrine origin. That as a logical sequence of the foregoing, operations upon the nerves are indicated in certain disorders and diseases of the stomach. That such operations are feasible, that in animals their results may be forecast, and that certain of them have been performed on man.

CARDIOVASCULAR DISORDERS

The Aftereffects of Diphtheria on the Heart.—The report of Jenner Hoskins (*Lancet*, June 12, 1926) is based on sixteen cases of diphtheria, in which the patients were sent to him for clinical and electrocardiographic examination on their discharge from the hospital. All these patients had definite signs of heart involvement during their stay in the hospital. Their ages varied from three to nineteen. The length of stay in the hospital averaged eighty-six days. In none of the cases were cardiac abnormalities noticed during the first week of the disease, the earliest recorded being on the eighth day and the latest on the thirteenth. The following were the principal abnormalities found while the patients were still in the hospital: Tachycardia, present in all but one case; cardiac enlargement was found in three cases; alteration of the first sound at the apex was noted in seven cases, reduplication being present in four cases; reduplication of the second sound at the apex was found in two cases; premature beats were noted in two cases, and both occurred in the fourth week.

On discharge, the sixteen patients differed from normal children of the same age in the following respects: 1, The higher rate of the heartbeat; 2, the presence of cardiac symptoms in half of the cases; 3, the diminished cardiac reserve; 4, the presence of heart abnormalities in almost all cases; 5, the changes in the electrocardiogram, notably the presence of the Q. R. S. complex in five of the cases, and the alteration in the character of the third lead.

The author believes that it is fair to assume that the effect of the diphtheritic toxin on the heart, in those cases where it has become involved during the course of the disease, is a more lasting one than is generally recognized. It is therefore of the utmost importance that patients in whom cardiac symptoms and abnormalities have been discovered during their stay in the hospital, shall be thoroughly examined, both clinically and electrocardiographically, on their discharge before being allowed to return to their ordinary avocations, and that if the heart is found to be still affected they should be kept under observation until it has either regained the normal or has reached a stationary condition of recovery.

Surgical Treatment of Angina Pectoris.—D. Danielopolu (*British Medical Journal*, January 30, 1926) maintains that in the Jonnesco method the division of certain nerves, such as the cardiac accelerator fibers, involves danger, while nerves which may be divided usefully and without injury are left untouched. With the author's method it is the former which are left intact, and many nerves—possibly more than in the Jonnesco operation—which contain sensory cardioaortic fibres, are severed. It is not prudent to continue this operation, which has been followed by fatal results, before trying a method which appears to be wholly harmless and probably very effective.

The author's operation has its contraindications; it should not be employed if signs of myocardial insufficiency are present, as, for example, when anginal attacks are complicated by pulmonary edema, which indicates the presence of extensive myocardial degeneration. Even so Jonnesco's operation would appear to be much more dangerous than the author's. The number of methods which the author advises may seem surprising but the methods are successive, each one perfecting a preceding one. Some proved excellent from the first, but in each new operation division of more sensory cardioaortic fibres has been attempted in order to make the benefit more complete. The operation, however, should be as complete as possible in each case, resection of the cervical sympathetic being supplemented by section of the vertebral nerve and the communicating branches, the second, third and fourth spinal nerves, the anastomoses connecting the superior cervical ganglian with the cranial nerves, the vagal fibres descending into the thorax, and of certain branches of the vagus, in so far as anatomical peculiarities or technical difficulties allow. Cervical sympathectomy alone is sometimes very effective, but even this may sometimes be impossible because of the general condition of the patient. In such cases treatment should include simple section of the cervical sympathetic bundle, with or without section of the vertebral nerve, intrathoracic branches of the vagus, and the communicating rami. The number of sensory cardioaortic fibres will be reduced and the pressor reflex, which is the primary cause of the anginal attacks, will be diminished. When clinical improvement has started the operation may be completed at a later date.

In addition to the classical angina pectoris, surgical treatment may be considered in abdominal angina. Some of these cases are only angina pectoris with an unusual pain distribution, and may be relieved by the surgical treatment applicable to ordinary angina pectoris; in other cases, however, a real abdominal syndrome exists, due to arteritis or atheroma in the abdominal aorta, the celiac trunk, or the gastrointestinal arteries. Here the syndrome is referable chiefly to sensory fibres supplying the abdominal viscera. To prevent the attacks in such cases the solar plexus must be treated.

The practical conclusion appears that surgical treatment of angina pectoris is of general application. Cases must be well selected, and the completeness of the operation will depend upon the patient's condition. The author cannot agree with Mackenzie, who has stated that anginal patients should never be treated surgically. The Jonnesco method involving the removal of the stellate ganglion may perhaps be abandoned, but the method which the author suggests is far more hopeful, and offers much promise in practice.

Necessity of Removing Bacterial Foci of Infection in the Treatment and Prevention of Endocarditis in Children.—Myer Solis-Cohen (*Archives of Pediatrics*, July, 1926) emphasizes the fact that infectious microorganisms, rather than diseased tissue, constitute a focus of infection. Removal of diseased tonsils and flushing and aeration of paranasal sinuses do not remove all the infecting microorganisms from the upper respiratory tract. To lessen the chances of reinfection of the endocardium, it is necessary to remove the bacterial focus of infection in cases of endocarditis. To eliminate a bacterial focus, sufficient antibodies must be developed to destroy the infecting microorganisms or restrain their growth or neutralize their toxins. Antibody production may be stimulated by the injection of specific antigens. To contain in sufficient quantity the specific antigens, the vaccine must consist chiefly of microorganisms that are infecting the patient. It is believed that organisms that are pathogenic for a patient, and hence infecting him, can be differentiated from organisms that are nonpathogenic for him, to which he stands in the relation of a carrier, by means of the pathogen-selective method of culture. It may be possible in many instances to prevent the occurrence of heart disease by removing bacterial foci of infection in cases of chorea, arthritis, tonsillitis, and other conditions where endocarditis is recognized as a possible complication.

Great Dilatation of the Left Auricle.—C. F. T. East (*Lancet*, June 19, 1926) states that in mitral stenosis it is usual to find some degree of dilatation of the left auricle together with some attempt at hypertrophy. The state of the chamber at autopsy must depend on the pressure inside it during life, and the condition of the wall after the carditis which affected it along with the mitral valve and pericardium. The left auricle attains a greater degree of dilatation than any other chamber of the heart for three reasons—because it has thin walls, has no safety valve into the great veins like the right auricle, and is being filled by both ventricles at once when there is mitral reflux.

The great transverse enlargement of the left auricle seems rather remarkable. In the slighter degrees of enlargement it extends backward under the bifurcation of the trachea. It can readily be seen when the patient is screened in the right oblique position as a rounded shadow projecting backward from the heart shadow into the retrocardiac space. A little larger and it fills up the space under the arch of the aorta. Cases have been reported in which it has pressed on and interfered with the function of the recurrent laryngeal nerve. It may also press on the esophagus. Very little enlargement takes place to the left. The arch of the aorta passes over the auricle, and then down, behind it, and a little to

the left of it. The left ventricle lies in front and to the left of it, and is in all probability enlarged. The spine lies behind it, so it enlarged to the right and rather forward. A very great increase in size occurs of that small piece of the wall of the left auricle that lies between the root of the right lung and the interauricular septum a little to the front.

The lesser degrees of enlargement can only be detected by röntgenographic examination in one of the oblique positions, preferably the right anterior oblique. Probably quite extensive degrees of dilatation occur not infrequently and are not detected because they give no physical signs. If the shadow projects to the right of the heart, as seen in an anteroposterior view, it may escape recognition as being that of the left auricle, unless the direction of its enlargement is borne in mind. It does not give its distinctive physical signs until it is right up against the chest wall. There is no doubt that oblique röntgenographic examination is most helpful in cases of obscure cardiac enlargement.

Mode of Death in Various Types of Heart Disease.—Frederick A. Willius (*American Journal of the Medical Sciences,* April, 1926) in a review of 330 cases in which death occurred as the direct result of cardiac disease, clinically or pathologically determined, the types were found to be as follows: Arteriosclerotic cardiac disease twenty-five per cent.; myocardial infarction, eleven per cent.; hypertensive cardiac disease, twelve per cent.; cardiac hypertrophy associated with obesity, 0.6 per cent.; acute myocarditis, 0.3 per cent.; cardiac failure from mechanical causes, 0.6 per cent.; chronic endocardial valvular disease, twenty-eight per cent.; bacterial endocarditis, nine per cent.; pericardial disease, five per cent.; cardiovascular syphilis, eight per cent.; congenital cardiac disease, one per cent. Sudden death occurred in 125 cases, thirty-eight per cent., while death from gradual cardiac failure occurred in 205 cases, sixty-two per cent. Embolic phenomena occurred in fifty-eight cases. Necropsy was performed in eighty-five per cent. of the cases reported.

Influenza Bacillus Endocarditis.—Ella Hutzler Oppenheimer (*Bulletin of the Johns Hopkins Hospital,* May, 1926) reports a case of endocarditis due to Bacillus influenzæ because the findings suggest very closely, clinically and pathologically, those of a viridans endocarditis. Not until blood cultures revealed the Pfeiffer bacillus was it suspected that the case was anything but a typical instance of viridans endocarditis, and at autopsy the lesions were indistinguishable. The patient was a young man of twenty-eight who one and a half years before admission had been refused life insurance for a "bad heart." Eleven months before admission he had suffered from a cold with severe shooting pains over his left side, suggestive of a cerebral accident. The case, while caused by the Pfeiffer bacillus, clinically showed the protracted course, cardiac disease, splenomegaly, hemorrhagic nephritis, eruption, fever and clubbing of the digits with an onset suggestive of a cerebral accident so characteristic of Streptococcus viridans disease. Anatomically, the type of the vegetations on the chronically diseased and thickened valves, the widespread petechiæ, infarcts and embolic nephritis fit in detail into the same picture.

Clinical Experience with Cardiazol—Conrad (*Fortschritte der Medizin,* No. 6, 1926) said that cardiazol was used on more than fifty patients in the gynecological section of the Rudolph Virchow Hospital, Berlin, mostly cases in which operation had been performed. Some of these patients were women who had been admitted to the hospital for sepsis following attempted abortion, and had heart and lung complications. No injurious byeffect and no cumulative action of the drug were observed after frequent subcutaneous injections for days at a time. The pulse in the case of one patient, with absence of radial pulse after a long operation, recovered within two minutes after subcutaneous injection of one ampule of cardiazol, and remained regular and strong under further injection at two hour intervals. From the second to the fourth day one ampule of cardiazol was given three times a day. Another patient had lost a great deal of blood and the pulse during operation became thready, very rapid and hardly detectable. Respiration was superficial. Three minutes after the subcutaneous injection of cardiazol there was a marked improvement in the pulse and the respiration became deeper. Under further doses of cardiazol the pulse fell the next day to between 80 and 90 and was strong and regular. Cardiazol gave excellent results in conditions of collapse resulting from long operations, great loss of blood and long anesthesias. The drug evidently acts directly on the heart. When given over a longer period a sort of digitalis pulse developed, the pulse became slower and more regular, the volume per beat increased and the blood pressure rose slightly. The author holds that an advantage of cardiazol which is particularly important in operative gynecology is the fact that, unlike camphor, it has no paralytic action on smooth muscle. Therefore Conrad prefers cardiazol as a heart stimulant after gynecological operation in which there is a peculiar tendency to paralysis of the intestine.

Changes in Ventricular Rate Associated with Stokes-Adams Attacks in Complete Heart Block.—C. E. K. Herapath (*Lancet,* March 27, 1926) reports a case in which a continuous electrocardiogram of the whole of a Stokes-Adams attack is reproduced. It suggests an explanation of the attacks of ventricular asystole, which attacks in a case of complete heart block where abolished by an injection of adrenalin.

In this case of complete heart block with a normal supraventricular rhythm an irritable focus develops in the right branch of the auriculoventricular bundle; in the early stages this produced occasional premature ventricular contractions, a little later this irritability increases and the focus produces a simple ventricular tachycardia which displaces the original rhythm. This tachycardia exhausts the rhythmicity of this newly formed pacemaker and ventricular asystole occurs. After a rest the old site of stimulus production tries to assume activity, but is again disturbed by the new rhythm, which slowly begins a rhythm of its own. After some time the old rhythm does manage to resume its activity, but it is soon overwhelmed by another attack of tachycardia from the new site of stimulus production, and so on. An injection of adrenalin is given, and this so stimulates the cells of the bundle that the old rhythm is once more made powerful enough to take control. In a few days this rhythm disappears and the new site of stimulus production permanently establishes its claim to be the ventricular pacemaker. No ventricular standstill occurs when this change is made, because the new rhythm is now capable of starting as promptly as necessary. There is nothing new in this explanation, but there is proof in the electrocardiographic tracings, and when more of these cases have been analyzed by this means an explanation of all the varying attacks of ventricular asystole may be found.

The Abuse of Rest in Cardiac Therapy.—William D. Reid (*Boston Medical and Surgical Journal,* June 3, 1926) contends that rest is too frequently prescribed in cardiac therapy. The unintended harmful effects that may follow the prescribing of rest to cardiac patients may be classified for the moment under three headings.

1. *Physical.*—It is well known that in the elderly, prolonged rest in bed has a very real danger in that it is sometimes difficult to get the patient out of bed again; congestion of the lungs and hypostatic pneumonia may result. Much loss of tone of the bodily musculature is prone to occur and is not always readily regained. It is also conceivable that there may be some loss of function of the various reflex mechanisms which do so much to perfect the circulation of the blood.

2. *Psychic.*—Ordering rest in bed in any or all heart conditions is sometimes the worst thing that can be done. To condemn the patient to idleness is to anchor and perpetuate any neurotic tendency. There may result a fixation of the idea of invalidism.

3. *Economic.*—It is a serious matter to prescribe a treatment which may cost an adult his position on which his livelihood depends. In children, it is true, the loss of time is less important as it merely means the loss of their class in school. In some children, however, this is attended with considerable psychic trauma. It seems fair to hold that a very definite benefit must be achieved to compensate for the loss of time involved.

Suitable exercise, it will be conceded, is part of good hygiene. Individuals affected by diseased hearts are handicapped; why deprive these handicapped persons of the benefit of exercise? Is it not true that the prescribing of rest is so helpful in some cases that these good results may be said to carry the burden of the all too frequent instances

where rest is neither indicated nor attended with any degree of benefit? It would seem that a similar situation exists as regards digitalis therapy, which is too often fruitlessly applied.

It is often held that the patient should be in bed when digitalization is being accomplished, but experience shows that in many instances this can be safely accomplished in ambulatory patients. Notwithstanding the fact that there are symptoms referable to the heart in the condition known as effort syndrome, irritable heart, and by various other terms, such as the soldier's heart, etc., which it is true is not in any proper sense actual heart disease, it was clearly shown in the recent war that many of these patients could be made fit by gradually increasing exercise. The successful hardening of the soldiers by exercise should not readily be forgotten in civil practice. Too much rest was the worst thing possible for these men. And finally, although it has been sufficiently indicated above that the writer believes that rest is often a valuable and sometimes an essential part of the therapeutics of heart disease, the reader is again cautioned against assuming that this paper deprecates all use of rest in cardiac therapy.

Cerebral Manifestations of Paroxysmal Tachycardia.—Arlie R. Barnes (*American Journal of the Medical Sciences*, April, 1926) found such cerebral manifestations as vertigo, hemianopsia, temporary blindness, fainting, falling with or without loss of consciousness, and epileptiform seizures in fifteen of the 104 cases of paroxysmal tachycardia which he studied. These manifestations occurred most frequently in cases in which the origin of the impulse and its propagation in the heart varied the greatest from normal. The presence of these manifestations does not affect the prognosis in attacks of paroxysmal tachycardia; the prognosis depends on the type and degree of the underlying cardiac damage.

SYPHILIS

Guides in Syphilis Therapy.—Leo Hauck (*Urologic and Cutaneous Review*, May, 1926) states that the advantage of the combination mode of treatment of syphilis is that the salvarsan plays the rôle of an intense, rapid destroyer of the spirochetes while mercury and bismuth, on the contrary, engage in a process of gradual destruction. The strongly parasiticidal property of salvarsan renders this substance suitable for the treatment of the early stage of syphilis. Bismuth is now considered to be of equal value as mercury, but cannot supplant it entirely. In the late stages the value of idodine is not to be depreciated.

The early diagnosis of syphilis is of the first importance. If the primary lesion will not yield spirochetes, it may be possible to demonstrate the spirochete by puncturing a lymph gland. A favorable prognosis may be made where treatment is started within three or four weeks after infection begins, in which case a single maximum unmixed salvarsan course of treatment or a combined salvarsan mercury or salvarsan bismuth course often suffices, or, if one would play safe, two such courses, to effect a quick and lasting cure. This may be assumed if a serum negative reaction before the beginning of the treatment does not change to positive during an observation of two years. The chances of a cure may be regarded as favorable, however, even in the seropositive primary stage and during the first few weeks of the secondary stage. But in such cases two, or better still, three courses of a combination course must be employed if a certain cure is to be effected.

The separate doses of salvarsan must not be too small or given at too great intervals apart. The first injection should consist of 0.15 or 0.3 gm. of neosalvarsan to determine the presence of an idiosyncrasy. If none is present, on the following day men are given 0.6 gm., women 0.45 gm. of neosalvarsan. These doses are again administered every fifth or fourth day until a total of five or six grams of neosalvarsan has been given. In addition the patients are given ten to fourteen injections of bismuth or a corresponding number of mercury injections. Or the mercury may be used by inunction. After an interval of four to six weeks, a second course of the same treatment is repeated, and two or three months later, a third course is given.

Such a course of intensive treatment will usually effect a cure, but there are cases where paralysis or tabes occurs in later years in spite of the treatment. In these cases the malaria treatment of general paralysis works very well. Recently the malaria treatment, preceded and followed by an intensive course of salvarsan, has been found to exert a favorable influence also upon the early stages of syphilis. The action of the malarial fever should be interpreted simply as a nonspecific elevation of the powers or as irritation therapy. The combination of ultraviolet light with chemotherapy may be explained as a similar effect. The favorable influence on syphilitic disease processes of nonspecific therapy is proved incontestably by the action of phlogetan, a mixture of disintegration products from certain albuminous substances.

The treatment of a syphilitic patient should not be stopped before a lumbar puncture is done. A syphilitic should be pronounced as probably cured only when after several years of a seronegative blood finding the cerebrospinal fluid also shows normal conditions. If the cerebrospinal fluid shows normal conditions the treatment may be discontinued after from three to five specific courses even though the serum reaction of the blood remains positive. Iodine serves very well in such cases. At certain intervals röntgenology should be employed in order to detect disease changes in the large bloodvessels at the beginning of their development so as to apply the appropriate treatment.

Continued Instead of Intermittent Treatment of Syphilis.—Johan Almquist (*Urologic and Cutaneous Review*, May, 1926) presents the results of continuous antisyphilitic treatment, using varied specifics arranged in alternating courses without any interruptions. Treatment is begun with salvarsan, beginning with 0.3 or 0.45 gm. every fifth day and gradually increasing this dosage up to 0.9 gm. during the course of six weeks until ten doses have been given. Immediately following this, a course of bismuth, or a similar course of absorbable mercury (usually mercury salicylate) is given every three days for ten doses during a period of one month. Bismuth and mercury may be given, one following the other during a period of two months, without intermission. The course of salvarsan is then again repeated and in turn another course of bismuth and mercury is given without intermission. In this manner it is possible to continue for a longer or shorter time. If there is no idiosyncrasy for mercury some insoluble form of mercury as blue ointment is given to get a prolonged action. If the patient shows little tolerance, potassium iodid, at least three gm. daily, is given for one to two months.

During the course of salvarsan treatment a Wassermann reaction is taken prior to every second or third injection. During the course of the bismuth and mercury injections a test at the beginning, in the middle and at the close of treatment, is sufficient. The period of treatment without interruption never exceeded fourteen months.

If proper precautions are taken to rid patients of gingival fissures or diseased tonsils or other pockets in the mucosa of the mouth, by removing the sources of infection and proper oral hygiene, stomatitis may be avoided, even though huge doses of mercury are administered. Colitis may also be prevented. To avoid symptoms of toxemia during continuous treatment, it is very necessary to pay special attention to the individual tolerance, and to modify the dose accordingly, especially with mercury. As mercury frequently induces a loss of weight, the body weight should be carefully and frequently controlled. Salvarsan produces an increase in body weight, especially with smaller doses. Bismuth has a somewhat similar effect upon the weight.

Inordinate Syphilis.—A. Galliot (*Urologic and Cutaneous Review*, May, 1926) recalls that syphilis is classically described as having a regular evolution: primary, secondary and tertiary periods and the period of visceral and nervous syphilis. Most of the cases correspond to that theoretical evolution, but sometimes syphilis occurs with a series of anomalous forms and great variations in the chronology of the lesions. These cases of inordinate syphilis are due, perhaps, to a peculiar virulence of the microbe, or maybe to special conditions of the host.

The chancre usually appears within twenty to forty-five days, but cases have been reported in which the chancre appeared sixty and even ninety-five days after exposure as a result of inadequate treatment. The same may be said of the secondary period. On the other hand, another form of syphilis exists which seems to run along at full speed. This is the form of malignant and precocious syphilis, in which the hypervirulence of infection goes full speed, the secondary manifestations invading the whole organism and rapidly ending in the tertiary form.

Other forms still exist where the evolution of syphilis is

quite anomalous, but these irregular evolutions can only be appreciated after a period of several years. Under this category we may place syphilis with malignant evolutions, called implacable syphilis, and others with benign evolution are called cryptosyphilis, or latent syphilis. Of the latter type the only symptom is the unchangeableness of the Wassermann reaction which remains always positive, in all cases, in spite of all kinds of treatment, even the most intensive. Implacable syphilis is found in two kinds of cases: 1, recent syphilis regularly and correctly treated from the primary or secondary period, or 2, the case may present itself as an old syphilis treated at the beginning more or less regularly and having remained latent for a long time a Wassermann reaction, generally made by chance, is positive and remains so in spite of treatment. It takes as in the preceding type, a previous or visceral form absolutely incurable.

There exists also another form of syphilis which, instead of being virulent, is benign. This form, which seems to be stopped in its evolution, is chiefly observed by making inquiries among old people who own to having had syphilis in their youth. The disease, at the beginning, was carelessly or not treated at all, and all during their lives—sometimes long—the patients have never had any specific manifestations, or from time to time have had very slight cutaneous lesions, promptly cured by mild treatment. In some peculiar cases the syphilis seems to be stopped in its evolution. Those are cryptosyphilis often discovered among pregnant women. The syphilis is highly toxic to the child, but very benign to the mother who perhaps, not having been treated during all her life, never shows the least manifestation of the disease, except for the numerous troubles in gestation. The women appear to be the socalled germ carriers.

It is very difficult to know what agency is responsible for those anomalies. Two hypotheses can be offered: Organism or medium, probably the latter.

Syphilitic Bronchopathies of the Second Period.—Jean Tissot (*Urologic and Cutaneous Review,* May, 1926) remarks that syphilitic bronchopathies of the second period are considered to be rare because not sufficient care is taken to detect them. He has been able to demonstrate that in every eighteen syphilitics having secondary lesions, twelve presented symptoms of subacute bronchitis, with coarse bronchial rales at the level of the hilum and hissing and sibilance at the apices without fever or expectoration, and this without the patients suspecting the presence of any affection of the respiratory passages.

On simple inspection one is often struck by the bad general condition of the patient who is emaciated and asthenic. There are the lesions of ordinary bronchitis, but a strikingly pronounced dyspnea. The expectoration is abundant, more mucous and foamy than purulent. In the morning upon awakening the expectoration is often bloody and during the day there is slight hemoptysis. Tuberculosis may be suspected, but no tubercle bacilli are demonstrable. Radioscopy shows a fanlike opacity proceeding from the hilum, the course of the bronchi marked and often grayish at the apex. Radiography confirms these pictures.

The author explains the hemoptysis by venous congestion and vasculoconjunctival hyperemia noticed in the course of the visceral localization of secondary syphilis.

These pulmonary complications improve rapidly under the influence of novarsenobenzol treatment, the arsenic at the same time improving the general condition. Iodids are interdicted in this condition. Morphine may be used for the dyspnea. The hemoptysis usually disappears with the antisyphilitic treatment.

Pregnancies as a Factor in the Prevention of Neurosyphilis.—H. C. Solomon (*American Journal of Syphilis,* January, 1926) studied the history of pregnancy in 559 syphilitic women thirty years of age or older, admitted to the Boston Psychopathic Hospital. These 559 cases were divided according to the diagnosis of paretic neurosyphilis, tabetic neurosyphilis, meningovascular neurosyphilis, and syphilis without central nervous system involvement. The results of the analysis showed that about forty-four per cent. of the women with paretic and tabetic neurosyphilis were nulliparæ in comparison with 26.5 per cent. of nulliparæ among the women who had syphilis but no evidence of nervous system involvement; also that pregnancies were considerably more frequent among the non-nervous system luetic patients than among the neurosyphilitics.

One of two conclusions may be drawn from these analyses. First, that women who develop neurosyphilis become less fertile than women infected with syphilis but without central nervous involvement, either because the former have a more serious type of infection or because they are infected with a different type of organism, namely, a neurotropic strain which tends to affect the childbearing potentialities of the individual; or, second, that women who become pregnant receive thereby a protection against the spirochete and its attack upon the nervous system.

The first hypothesis has been mentioned in the literature often enough. The second alternative is very suggestive and what value it has is opposed to the explanation of neurosyphilis wholly on the basis of a neurotropic strain of spirochetes. One may paraphrase the idea to read in more general terms, as follows: Changes in the metabolism of a syphilitic patient may affect his ability to protect the nervous system from the attacks of the spirochete. Pregnancy, with its metabolic concomitances may be an example.

Syphilitic Myocarditis in the Rabbit.—Wade H. Brown and Louise Pearce (*Journal of Experimental Medicine,* April, 1926) found in the course of routine postmortem examination of rabbits infected with Treponema pallidum six cases of pronounced granulomatous myocarditis. Treponemata were not discovered in the lesions, but the clinical history, and the gross and microscopic appearance of the lesions seemed to warrant a diagnosis of syphilitic myocarditis. The lesions measured one or more centimetres in diameter, and histologically were practically identical with those described by Warthin in cases of syphilitic myocarditis in man. These are the first cases of syphilitic myocarditis or of visceral syphilis in the rabbit that have been reported.

Gummatous Osteoperiostitis of the Skull in Congenital Syphilis.—Ethel C. Dunham (*American Journal of Diseases of Children,* November, 1925) reports the occurrence of gumma of the skull in two children. The bones and skin were involved without evidence of involvement of the brain or meninges. The lesions healed rapidly under general antisyphilitic treatment. In spite of the formation of sequestrums, surgical treatment was not necessary to bring about complete healing, as evidenced locally and in the röntgen ray. Healing of the bones took place more slowly than healing of skin lesions, but was finally complete. While gummas of the skull occurred in the cases reported as a manifestation of late congenital syphilis, they may occur early, as in the case reported by Ambrus.

Conjugal Syphilis of the Nervous System.—Alfred Gordon (*American Journal of Syphilis,* April, 1926) states that in an attempt to sum up the entire subject of conjugal syphilis of the nervous system, several etiological element should be taken into consideration. First, the clinical and experimental evidences favor the conception of a special neurotropic virus different in its character from the demotropic virus. Second, a special innate predisposition for organic alteration of the central nervous system. Third, the intensity of the use or overfatigue of the cerebral centres of the spinal axis. Fourth, conjugal neurosyphilis includes not only the parenchymatous forms (tabes, paresis) but also the vascular or meningeal type in which the nervous disturbances appear secondarily (Argyll Robertson pupil, abolition of Achilles tendon reflexes, lymphocytosis or other abnormalities of the cerebrospinal fluid).

Diffuse Syphilitic Infiltration of the Stomach.—I. Eisenklam (*Wiener klinische Wochenschrift,* February 11, 1926) states that the clinical picture of syphilitic disease and ulceration of the stomach corresponds to that of simple ulcer and of cancer. Pains at the xiphoid process, in addition to backache, intolerance of the stomach, vomiting, possible gastric hemorrhages of varying intensity, and emaciation, are all present both in specific as well as in the common affections of the stomach. The chief symptoms, namely, anacidity of hypoacidity, achylia and cachexia, show nothing characteristic. The hyperplastic thickening of the stomach produces clinical pictures, which depend largely upon the localization of the greatest amount of the changes in the gastric wall.

There is no site of predilection for syphilis in the stomach. It usually takes the form of diffuse changes which infiltrate the gastric submucosa. Inasmuch as the pyloric portion of

the stomach produces the most prominent symptoms in the clinical picture, this form of syphilis of the stomach is usually considered as a hypertrophic stenosis of the pylorus, even though the stenosis constitutes only a symptom. These are the cases which, aside from the true gummatous tumors, pass under the clinical and roentgenologic diagnosis of stenosis of the pylorus and are referred to the surgeon as neoplasm at the pylorus.

The diagnosis of syphilitic disease of the stomach is relatively easy when other luetic symptoms are clinically demonstrable, but this is usually not the case. Syphilis of the stomach may or may not be associated with syphilis of the liver and intestines. A negative Wassermann reaction does not rule out syphilis. The therapeutic test with iodides or arsphenamin may be of value. Röntgenography is not of much diagnostic value and may even be misleading, often suggesting the diagnosis of carcinoma. If only the diagnosis is though of, the diagnosis will be made more often.

The prognosis in regard to life seems to be one of doubt. The majority of the known cases have been diagnosed at necropsy, and consequently it is impossible to determine whether the patients died from the syphilis of the stomach or whether the latter was only a part of the fatal cause. In some cases the disease is beyond control.

Treatment of Syphilis of the Central Nervous System.—Frederic J. Farnell (*American Journal of Syphilis,* April, 1926) describes his method of treatment in the following types of cases of syphilis of the central nervous system: early cases of tabes dorsalis in which response to ten to twenty intravenous injections was poor; special cases of early syphilis of the cord, where difficulty in urination was the initial disorder; fairly advanced cases of combined sclerosis due to syphilis with poor bladder control; early cases of multiple sclerosis with bladder symptoms; cases of the exudative form of meningoencephalitis with a tabetic symptom complex.

The author's technic is the following: From twenty to fifty c. c. of the salvarsanized serum are prepared in the usual manner. The Swift-Ellis method is employed. The needle is introduced into the first, second, or third lumbar space to such a distance that it is considered outside of the dural sac. The syringe is then attached to the needle, and by slow but firm pressure the fluid is introduced into the extradural space, taking from three to seven minutes to avoid unpleasant symptoms. The needle is then withdrawn, and the technic followed as in the usual run of spinal puncture cases. When it is definitely decided that the pain is secondary to an intervertebral neuritis, rather than a radiculitis (a subarachnoidal position), twenty to fifty c. c. of isotonic salt solution is instilled into the epidural space. Many such cases of tabetic pain have been relieved by hypertonic iodides intravenously. A ten per cent. solution is made, using one hundred c. c. of distilled water, which is autoclaved. The intravenous route avoids irritation of the digestive tract. For those patients who do not respond to salvarsan intravenously and iodides by mouth, the author recommends a series of intravenous hypertonic solutions of sodium iodide at intervals of five days. Tryparsamide is used as an associative method of treatment.

Syphilitic Chancres Retarded Spontaneously or by Antisyphilitic Treatment.—Henri Gougerot (*Urologic and* Cutaneous Review, May, 1926) states that one encounters retarded chancres under two different series of conditions: In the first series the incubation is prolonged without apparent cause, and in the second series the incubation is retarded by an antisyphilitic treatment of a curative sort administered in all old syphilis either acquired or hereditary. The incubation may be also retarded by a prophylactic antisyphilitic treatment.

In regard to the first series one should bear in mind these abnormally long incubations even in the absence of treatment, and to observe for a long time persons suspected of being infected. Clinical and serological examinations should be made repeatedly for twelve months. The diagnosis of syphilis cannot be rejected because the incubation period exceeds one hundred days. These cases prove that there exists much attenuated syphilis, not betraying itself by any sign in the beginning, but later, on account of lack of treatment, continuing to develop and is transmitted conjugally or to descendants and cause grave visceral lesions in the patient himself, such as neuroses.

In the second type the typical infection is simply retarded. There is a chancre of usual aspect and intensity with adenitis. The Wassermann reaction appears more or less quickly. More often, apparently, the retarded syphilis is attenuated. The chancre may be small but last only a few days. There may even be no adenitis. The chancre may even be absent, without any visible lesion or palpable glands, but the seroreaction made in a series becomes positive. It is syphilis without chancre or bubo. In some the syphilis reveals itself first in secondary symptoms. One should then mistrust the clinical and serologic success which is almost constant with prophylactic treatment. The Wassermann reaction may be negative in spite of the existence of syphilis.

Sometimes the arsenical treatment is insufficient although surpassing the doses at first recommended. Sometimes the treatment is too tardy. Then there are the cases of arsenoresistant syphilitic virus.

The following rules of treatment should, therefore, be followed: 1. It requires an intense arsenical treatment with large doses up to 0.9 gm. of neosalvarsan or of sulpharsenol at short intervals of three to seven days, with a total dose of six to seven gm. if possible, with pauses as brief as possible (three or four weeks), with a second strong arsenical course and then a bismuth and mercury course of six months.

2. One should from the start combine as soon as possible bismuth with arsenic to avoid arseno resistance.

3. There is required a prolonged clinical and serologic oversight of all who have received prophylactic treatment for two to four years from the date of commencement of treatment, just as long as if the chancre had appeared.

4. One should practice reactivation before being assured of the abortion of syphilis, and not be content with a negative Wassermann reaction even in a series.

Spirocide (Stovarsol) in Syphilis.—M. Oppenheim (*Wiener klinische Wochenschrift,* May 27, 1926) asserts that there is no antisyphilitic remedy that may be given by mouth that can equal or even approach the value of stovarsol; in the rapidity of its action it is comparable only with salvarsan. Under proper administration it is noninjurious to both the gastrointestinal canal and the entire organism. It is usually associated with an increase in weight. After the first administration there is usually a high fever and occasionally a toxic erythema which never goes into a dermatitis. Usually it is followed by a Herxheimer reaction. All of the cases of seronegative primary syphilis treated with stovarsol and bismuth preparations for abortive purposes remained negative after one and a half years both in regard to the general symptoms and seroreaction. Secondary syphilis treated with spirocide alone soon become asymptomatic and show little tendency to recurrences; combined treatment gives the same results as neosalvarsan. Tertiary syphilis and congenital syphilis of infancy is influenced very favorably and rapidly. Infants bear this drug excellently. The seroreactions become negative less rapidly than with salvarsan treatment, but after four to six months of spirocide treatment they behave exactly like the cases treated with salvarsan. Lumbar punctates behave like cases after combined neosalvarsan treatment.

Spirocide has failed in skin diseases: chronic pemphigus vulgaris, acute and chronic psoriasis vulgaris, lichen ruber planus, erythrodermias, chronic eczemas and neurodermatides showed no marked improvement—a behavior similar to that of salvarsan.

The author believes that spirocide deserves a place in the therapy of syphilis. It cannot replace salvarsan, but it is an excellent substitute in cases where salvarsan cannot or must not be given. The most effective dosage has not yet been determined. Oppenheim follows that proposed by Levaditi: upon three successive days the patient is given eight or nine tablets a day on an empty stomach, with a three days' rest. As a rule, one tablet is given for each kilogram of weight. It will probably assume a place of first importance in infantile syphilis, provided the initial dose is small enough. In aphthous stomatitis of small children a local application (one tablet to ten c. c. of water or glycerin) has given very good results; also in specific leucoplakia with erosions and ulcerations. In syphilis of the internal organs it often produces focal reactions (pain) and general reactions (fever), which facts may be of diagnostic significance. It is also borne well in syphilitic aortitis. In every case where a syphilitic infection is suspected, spirocide may be given as a prophylactic, and the subsequent treatment should be continued for at least one year. In the syphilis of infants it is a specific of the first importance.

PEDIATRICS

Nonendemic Enlargement of the Thyroid Gland in Children.—Apart from endemic goitre and other hyperthyroid conditions, H. Finkelstein recognizes (*Jahreskurse für Arzliche Fortbildung,* June, 1925, vol. 3, page 1, as quoted in *The Endocrine Survey,* April, 1926, vol. 3, page 130) a form of simple enlargement not uncommon in the period of most rapid growth. As in most thyroid disturbances, girls are more subject than boys. In Germany tryroid enlargement is more common among grammar school children of the middle classes than among the poorer children who attend municipal schools. In about half the cases the entire thyroid is affected by the hyperplasia: next in frequency is the isthmus or the right lobe alone, while isolated involvement of the medial or the left lobe is exceptional. Normally from the fifth year of life the growth of the gland is accelerated, and at puberty it weighs three times as much as in infancy. It is noticed that children and adolescents with enlarged thyroid glands reach a greater height as a rule than normal individuals. Finkelstein believes abnormal predisposition to growth is the primary factor and the hyperplasia a sequel. Since girls grow more rapidly between the ages of ten and fourteen than do boys, this may account for the larger incidence of thyroid hypertrophy in girls. Secondary sex characteristics are known to be accelerated in girls with enlarged thyroid glands, and both conditions probably depend on changes in the sexual organs. These patients tolerate iodine very well. Ovarian substance has been employed with benefit, although in exophthalmic goitre it may cause tachycardia. Quinine and arsenic prove useful in children with severe cardiovascular excitement, and phosphorus also exerts a sedative influence and causes increase in weight.

Cretinism.—A follow-up report of eight cases of cretinism is given by Charles Gilmore Kerley, *(Archives of Pediatrics,* February, 1926). In a boy of fourteen years and a girl of ten the dose of desiccated thyroid has been gradually diminished and Dr. Kerley thinks it reasonable to assume that in these two children the thyroid function will be completely established. In the other six, who also represent thyroid dysfunction, the dose has been increased from fifty to seventy-five per cent. Indications for increasing the dose have been irritability, sleeplessness, bedwetting, a tendency to nasal hemorrhage. Each case regulates its own dose. When an insufficient amount of thyroid is given, or when it is discontinued, the child becomes physically inactive and mentally dull. It is evident that the thyroid secretion is utilized as rapidly as it is produced as the change when the thyroid medication is discontinued is noticeable in twenty-four hours. It would seem that the ultimate results of thyroid feeding in cases of complete absence of the thyroid gland are not as favorable as the early improvement would seem to warrant. In those who have reached adolescence, the mental capacity is decidely defective as shown by the records in these cases.

The Picture of Whooping Cough.—E. Ziegler (*Schweizerische medizinische Wochenschrift,* January 30, 1926) found that in the beginning of whooping cough the appearance of an increase in the total number of leucocytes with a simultaneous increase of the absolute and very often also of the relative number of lymphocytes is typical. These changes have their beginning in the catarrhal stage and usually reach their maximum during the first few days of the convulsive stage. Generally in the course of five to six weeks later there follows a gradual recession to normal figures. The lymphocytosis in whooping cough is brought about by infectious-toxic causes. The mechanical factor, the expression of the lymphocytes by the attacks, plays only a subordinate part. It is very unlikely that a postinfectious lymphocytosis occurs.

The blood findings are important, in the first place, in the early stage, in which it was found to be positive in about seventy to eighty per cent. of cases on continuous examination, and secondly, in the beginning of the convulsive stage, when after a single examination no convulsive attack may have as yet occurred, and particularly in the differential diagnosis from the pseudopertussis of grippe and in attacks of bronchial gland tuberculosis. The blood findings are often of no value diagnostically in very slight and abortive cases and mostly in the declining stage.

The prognostic significance lies in the fact that the disappearance of the lymphocytosis indicates well the transition from the infectious-toxic stage to the psychogenic-neurotic stage. The severity of the individual case cannot be judged always by the grade of the lymphocytosis.

With the development of pulmonary complications there is a relative and absolute increase of the neutrophiles with a displacement of the same to the left without any diminution of the lymphocytes. In the case of a combination with other infections there develop more or less typical "interfering blood pictures."

Hookworm Infestation.—An excellent plan for control measures in regard to hookworm disease is suggested by W. G. Smillie, M. D., and D. L. Augustine, Sc.D. (*American Journal of Diseases of Children,* February, 1926) at the end of a valuable study of intensity of infestation in 1,821 children, 1,280 being white and 541 negro. Heavy hookworm infestation (500 Necator americanus or over) is found to cause marked retardation in the normal growth in height and weight and lowers the hemoglobin of children of school age. An intensity of 100 to 500 hookworms also produces measurable injury and is true hookworm disease. Light infestation (from 1 to 100 Necator americanus) produces no measurable retardation in the normal development of children of school age, nor is the hemoglobin of this group reduced to any degree. An infestation of 25 worms or less represents a carrier state, is not true hookworm disease and should not receive hookworm treatment. Other interesting points came to light upon comparing the charts of the white and the negro children. The latter had a markedly lower vital capacity as measured by the Sanborn wet spirometer, but both normal and infected negro children had a slightly higher hemoglobin than white children.

Hemorrhagic Measles with Encephalitis.—Harry Lowenburg and Abraham Lincoln Schaller (*Archives of Pediatrics,* Vol. 43, February, 1926.) were unable to find in the literature any reference to the use of convalescent serum as a therapeutic agent in the treatment either of measles or of any of its complications. They present a case in a little girl four and one half years old. The following conclusions convey only a slight idea of the great efforts made to save the child: A. When encephalitis which is more common in the hemorrhagic type of measles is suspected, lumbar puncture should be performed. B. The efficacy of convalescent measles serum, injected intraspinously, intravenously and intramuscularly in encephalitis complicating measles has not been proved but is worthy of further trial; it produces no reaction of anaphylaxis and is entirely harmless; is should be used early—as soon as symptoms, proved by lumbar puncture, indicate involvement of the brain and its membranes; large amounts are necessary. C. Encephalitis occurring in measles may proceed to full recovery.

The Basal Metabolism After Pneumonia.—Bela Schick, Philip Cohen and Isabelle Beck (*American Journal of Diseases of Children,* Vol. 31, February, 1926) found from data secured from twenty-one children over five years of age that after pneumonia, there is not infrequently a low basal metabolism which rises to normal in from one to three weeks, occasionally longer, which is associated with a slow pulse rate. Less frequently a high postinfectious basal metabolism was encountered which declined to normal in from two to three weeks. These two findings may be related, the authors feel, to a marked tendency to obesity or leanness, or a stunting of the growth processes, occuring after infections.

Index of Refraction of Breast Milk Serum.—It is always necessary to protect against fraud. Now that "breast milk dairying" is assuming considerable proportions, lest the product be diluted with water or cow's milk by the unscrupulous, Charles I. Solomon and Alfred T. Shohl (*American Journal of Diseases of Children,* February, 1926) propose a means of detection by determination of the index of refraction. By this method, the addition to breast milk of eleven per cent. of water and twenty per cent., or more, of cows' milk may be simply, rapidly and accurately detected.

Trypsin Secretion of Infants.—There seems to be a possibility of a pathogenic relationship between the increased trypsin secretion and some symptoms of rickets, according to T. Lukacs (*American Journal of Diseases of Children,* February, 1926).

Influence of Acidified Milk on Duodenal Function in Infants.—Lloyd Arnold (*American Journal of Diseases of Children,* May, 1926) presents a brief paper on the influence of acidified milk on duodenal function in infants.

Medicolegal Notes.

TAXATION OF NURSES' HOME ATTACHED TO HOSPITAL

The Mississippi Supreme Court holds, Johnson v. Mississippi Baptist Hospital, 106 So. 1, that where a hospital maintains a home for nurses employed in its services, where they live when not on duty, which nurses' home is situated on a separate lot or lots from that on which the hospital building is situated, and is not used exclusively for the purposes of the hospital within the meaning of Mississippi Code 1906, § 4251 (d), the property is subject to taxation, notwithstanding that the hospital gives a course of instruction to the nurses employed by it in the proper nursing and treatment of patients.

SUFFICIENT INDICTMENT UNDER ALABAMA MEDICAL PRACTICE ACT

The Alabama Court of Appeals, Robinson v. State, 106 So. 53, holds that the Alabama medical statute is designed to prevent the treatment of diseases of human beings by any system whatsoever, unless the party so engaged has first obtained a certificate of qualification from the state board of medical examiners, and therefore an indictment charging that defendant treated or offered to treat human diseases "by a system known as chiropractic for a reward, such system being practised by men known as chiropractors, without first having obtained a certificate of qualification from the state board of medical examiners" was not demurrable for failure to sufficiently describe the system or its method of practice, or failure to aver that that is unknown.

In Robinson v. State, 106 So. 203, the same court holds that all that is necessary to charge violation of the Alabama statute, Code 1907, § 7564, as amended by Acts, 1915, p 661, is an averment that defendant treated human diseases without having obtained the required certificate, and an averment that it is done by a system known as chiropractic is not necessary. Such an averment, though subject to proper demurrer, it is held, does not vitiate the indictment.

MALPRACTICE MUST BE PROVED—CAUSES OF ACTION AGAINST TWO PHYSICIANS ACTING SEPARATELY HELD IMPROPERLY JOINED

The Alabama Court of Appeals holds, Wilder v. Shannon, 106, So. 69, that in a malpractice action the plaintiff has the burden of proof of, 1, negligence and 2, that the injuries suffered were the proximate results thereof. This burden was not discharged where the overwhelming weight of the evidence was to the effect that whatever injuries the plaintiff may have suffered "were the direct result of the unprecedented flu epidemic that swept over the country at the time of the death of her testate," on October 5, 1918.

The action was in tort against two physicians jointly. There was no evidence showing or tending to show any community of design or interest existing between them. Any wrongs committed by either of them were apparently entirely separate and distinct from any committed by the other, and no reason appeared for joining them as defendants. Judgment for plaintiff was reversed and a new trial ordered.

ANSWER HELD RESPONSIVE TO HYPOTHETICAL QUESTION AS TO EFFECT OF CONCENTRATED LYE

In an action for injuries sustained by plaintiff while using concentrated lye in washing windows for defendant, two physicians testified as experts, and in a hypothetical question submitted they were asked to assume that concentrated lye and hot water were used, and, on this assumption, were asked if this could have caused the plaintiff's injury. In answering the question they stated that a strong solution of lye would be required to inflict such an injury as plaintiff sustained. The objection was made that the answer was not responsive to the question. The Arkansas Supreme Court held, Wilson & Co. v. Smith, 278 S. W. 31, that the answer was responsive to the question, which implied that the lye possessed burning qualities and did not exclude the idea that a strong solution had been used.

SCHOOL BOARD COMMITTEE MEMBER HELD INELIGIBLE FOR POSITION OF SCHOOL PHYSICIAN

The Supreme Judicial Court of Massachusetts holds, Barrett v. City of Medford, 150 N. E. 159, that a member of a school committee is ineligible to appoint as school physician or medical inspector, the duties of the two offices being incompatible. The court says: "Having in mind that a member of either branch of a city council or of a municipal board of a city is not permitted to be personally interested directly or indirectly in a contract made by the city council, or other branch thereof, or by such board, or by authority derived therefrom, in which the city is an interested party, Mass. Gen. Laws, c. 268, Sec. 9; that no "member of the city council shall, during the term for which he was chosen . . . be eligible to any office the salary of which is payable by the city," Gen. Laws, c. 39, Sec. 8; that a board of health of a city, who are authorized to appoint a quarantine physician under an ordinance giving him a compensation fixed by the city council, may not appoint one of their own members such quarantine physician, Gaw v. Ashley, 195 Mass., 173; that no member of a school committee shall be eligible to serve as teacher or superintendent in the public schools, St. 1904, c. 173; we think a school committee, in the absence of a statute permitting it, cannot elect one of themselves to the salaried office of school physician. The duties he is to perform as physician are incompatible with the supervisory duties which as a member of the committee he should exercise over the incumbent of the office of school physician. Consistently he cannot be master and servant."

The court also pointed out that the superintendent of schools might hold his office by a deciding vote of the member whom he may subsequently nominate for school physician, with an accompanying recommendation of a stated salary for the incumbent of that office.

LAYMEN'S TESTIMONY AS TO EXISTENCE OF DISEASES HELD INADMISSIBLE

In an action on an insurance policy the Kentucky Court of Appeals held, Sovereign Camp W. O. W. v. Morris, 278 S. W. 554, that testimony of lay witnesses that the insured had never had any disease of the heart or certain other diseases stated in the application was incompetent and prejudicial.

If within his knowledge, the court said, a layman may testify as to the strength, vigor, and apparent physical condition of another person, and as to the presence or absence in such person of symptoms indicating disease; also, some forms of disease are so common and so well understood as to be within the knowledge of a layman; but he cannot diagnose diseases, or testify as an expert in reference thereto. To illustrate: The witnesses in this case were not qualified to testify that the applicant did not have heart trouble or stomach trouble, but evidence of nature and symptoms of these diseases could have been proved by a physician, and these witnesses then could have testified as to the presence or absence of such symptoms.

The Use of Vaccines and Sera in Communicable Diseases*

RALPH OAKLEY CLOCK, M.D., F.A.C.P.

Pearl River, New York

The use of vaccines and sera in the prevention and treatment of disease dates from the introduction of diphtheria antitoxin by Behring in 1893, and from the application of antityphoid vaccination by Wright in 1896. The success of both of these remedies has firmly established them as invaluable agents in the therapeutic armamentarium, and has served to point the way to the development of similar products for the prevention and treatment of other diseases.

In the development of vaccines and sera, scientific investigation and experimentation have necessarily preceded clinical trials of those products which have proved to be of permanent value. Laboratory research and clinical observation should go hand in hand, each acting as a control on the other; for not only is it unscientific but it is an imposition on the profession to submit a vaccine or serum for clinical trial without successful preliminary laboratory investigation of its probable value.

The great practical value of sera lies in their therapeutic or curative properties; but in the case of vaccines, their main field of usefulness is protective. In considering the practical application of these products, the various diseases will be discussed in alphabetical order.

DIPHTHERIA

The prevention and treatment of diphtheria was discussed so freely at the 1925 Institute that I shall mention this disease only to urge the universal application of toxin-antitoxin for immunizing all children of preschool and school ages; and to recommend, to those of you who are called upon to treat diphtheria, that you adopt the policy of administering antitoxin early and in one dose of sufficient amount to control the entire course of the disease.

EPIDEMIC MENINGITIS

Epidemic meningitis or cerebrospinal fever has occurred in sporadic or epidemic form almost continuously since the world-wide epidemic of 1904. Prior to the use of serum, the mortality recorded in this country was about eighty per cent. Since the introduction of antimeningococcic serum in 1906, the gross mortality has been reduced to about thirty per cent.

To secure the best results from serum treatment, the following principles should be observed: 1. The serum should be injected as early as possible. 2. Serum should be injected by gravity into the spinal canal between the third and fourth lumbar vertebræ, or into the lateral ventricles through the open fontanelle so that it will come directly in contact with the meningococci. 3. The serum must be constantly present in as great concentration as possible, and, for this reason, should be injected at frequent intervals and in as large amounts as are safe. 4. Serum treatment should be discontinued only after the disappearance of the bacteria, and after improvement in the general condition of the patient.

In a suspected case of epidemic meningitis, lumbar puncture should be performed; and, if cloudy fluid is obtained, it is presumptive evidence of meningococcic infection and the serum should be administered without waiting for a bacteriological report. If the infection proves to be due to some other species of bacteria, no harm would have been done.

Dose.—In cases of average severity seen within the first three days, the serum should be given daily for three or four doses; or if of greater severity, at intervals of twelve hours for three or four doses then daily thereafter. The proper method of giving antimeningococcic serum is by the gravity method of intraspinal injection, following lumbar puncture and withdrawal of cerebrospinal fluid. The amount of serum introduced should be less by from five to ten c. c. than the volume of cerebrospinal fluid withdrawn by lumbar puncture. In infants and children, the dose of serum varies from five to twenty c.c.; for adults, from thirty to sixty c.c. Symptoms of shock during the intraspinal injection of serum are best treated by raising the patient's head and immediately removing fluid from the spinal canal. In addition to the intraspinal treatment, an intravenous dose of fifty to one hundred c.c. given at the outset of the disease and repeated once or twice during the acute stage may possibly prevent complications due to the entrance of meningococci into the blood stream.

MEASLES

Measles is universal, so that many people consider it a trivial disease; but as a cause of death in

*Lecture delivered at the New England Health Institute in Concord, N. H., held September 27 to October 1, 1926, under the auspices of the United States Public Health Service, the New England State Health Departments, the Yale and Harvard Schools of Public Health, and the Departments of Public Health and Biology of the Massachusetts Institute of Technology and Simmons College.

Copyright, 1926, by A. R. Elliott Publishing Company.

children, it ranks second among the acute contagious diseases. Therefore, some method of protection against measles is needed, especially for children under five years of age; because, if the disease could be prevented until later in childhood the mortality would be considerably reduced.

Recent discoveries.—At the present time a number of bacteriologists are making an intense effort to solve the problem of the etiology of measles. Recently, Ferry (1) isolated a streptococcus which he believes is the specific cause of this disease. From this organism he prepared a soluble toxin for use as a skin test and as an immunizing agent and, by immunizing animals with this toxin, he prepared an antitoxin. Culturally, this microorganism appears to be the same as that first described in 1917 by Tunnicliff (2) but the organisms do not give the same serological reactions. Within the course of a few months, the probable discoveries of Tunnicliff and Ferry should be developed to a point which, if they prove to be correct, will lead to the development of products which can be adapted to general distribution for the needs of the practicing physician.

Convalescent serum.—While waiting for confirmation of these discoveries and the development of a vaccine and antitoxin, we must depend upon serum from convalescent measles patients. This has been successfullly applied in several thousand cases, both in this country and abroad. The use of convalescent serum in a child that has been exposed to measles may prevent the development of the disease, or it may modify the severity of the attack, or it may fail entirely of any effect. The blood is usually drawn between the seventh and twenty-first day after defervescence of fever; but the efficiency of the serum is not markedly diminished if the blood is drawn three months after the occurrence of the disease, and storage in the icebox for six months does not appreciably alter its usefulness.

Dose.—For children under three years of age, 6 c.c. of convalescent serum is injected intramuscularly; while older children receive from six to ten c.c. This dose is sufficient, as a rule, to prevent the development of the disease in children who have been exposed for less than five days to measles. If it does not prevent the disease, it almost certainly modifies the attack so that it is very mild and not likely to lead to complications. The serum gives immunity for only two to four weeks, but in the modified cases there is lasting immunity.

The prompt use of convalescent serum will prevent serious outbreaks of measles in institutions, and thus prevent the development of complicating pneumonias.

PNEUMONIA

Prophylactic vaccination.—Although pneumonia is a prevalent disease, yet at present it does not justify a general and indiscriminate use of pneumococcus vaccine. There would seem to be two particular indications, however, for prophylactic vaccination against pneumonia: 1. For persons who are very susceptible to pneumonia and who suffer from repeated attacks of the disease. 2. For large groups of persons who are living together under abnormal conditions, such as recruits in time of war. In previous wars, intestinal infections were the chief menace to health. In the World War, pneumonia was the most serious of all infections and caused the greatest loss of life.

Pneumococcus vaccine could probably be used with benefit in the case of industrial workers, such as day laborers, truck drivers, chauffeurs, firemen, and policemen, who are constantly exposed to cold and wet; while the advisability of immunizing nurses, physicians, and relatives who come in contact with a pneumonia patient is a question which has not received much attention.

Injections of pneumococcus vaccine into monkeys produce an active immunity against experimental pneumonia and, when given in adequate doses, confers immunity against pneumococcus pneumonia in man. The evidence of such immunity rests on statistical studies and on the demonstration of immune bodies in the blood of those immunized with the vaccine.

Pneumococcus vaccine has been used with success among the mine workers of South Africa, and, during the World War, it was extensively used in some of the American army training camps as a prophylactic against lobar pneumonia. At Camp Upton, New York, Cecil (3) vaccinated 12,519 men against Types I, II and III pneumococcus. The men were observed for a period of ten weeks after vaccination and, during that time, no cases of pneumonia of the three types vaccinated against occurred among the men. In a control of approximately 20,000 men, there were twenty-six cases of Types I, II and III pneumonia during the same period. Numerous other statistical data could be cited to show the value of the vaccine.

Dose.—In civil life, vaccination against pneumonia is carried out with a vaccine consisting of equal parts of Types I, II and III pneumococcus. Three injections are given subcutaneously at intervals of one week, the first dose consisting of four and a half billion, the second and third doses each containing nine billion organisms.

Reactions.—Local and general reactions vary considerably in different persons, but the smaller the dose the less the reaction. Hence, if circumstances permit, it is desirable to divide the total dose into four or five injections.

Serum treatment.—The history of antipneumococcic serum affords a striking example of the difficulties and unforeseen pitfalls that may be encountered in the development of remedies of this class. Soon after the demonstration of the causal relation of the pneumococcus to lobar pneumonia, a serum was made by immunizing animals and such a serum was shown to protect other animals against pneumococcus infection. The serum was then used clinically and soon favorable reports appeared but others were doubtful or unfavorable. The serum was used for years until the weight of clinical opinion caused its abandonment as of no value in pneumonia.

Classification.—In 1910, it was discovered that the pneumococci are not a single species of bacteria but that there are actually several types or varieties in the United States, all of which were formerly classed together. At present what we call Types I, II and III pneumococci (4) are easily distinguished by laboratory tests, and all pneumococci not falling into these three types are classed together as Group IV. This group differs from the three type classes in not

being a single species but a heterogenous mixture of pneumococci.

The gain to therapeutics of this classification is due to the fact that a therapeutically active serum has been produced only against Type I pneumococcus infection, and this serum is not effective against infections caused by the other types of pneumococci. Therefore, in order to treat pneumonia rationally and scientifically with antipneumococcic serum, its application must be confined to cases of Type I pneumococcus pneumonia, proved such by laboratory tests; and only these cases may be treated with Type I antipneumococcic serum.

Dose.—In all cases of acute lobar pneumonia due to Type I pneumococcus, Type I serum is indicated and should be given as early in the disease as possible after the type of pneumococcus has been determined. The serum is best administered intravenously in an initial dose of not less than one hundred c.c., and this dose should be repeated every eight hours until the fall of temperature and subsidence of symptoms indicate that the infection has been overcome. In the average case, the total amount of serum required is 300 c.c. The serum should be warmed to body temperature and injected slowly.

Results.—The effectiveness of the serum is indicated, 1, by the blood of the patient being rendered sterile after injection of the serum; 2, by the arrest of the progress of the local lesion in the lung; 3, by subsidence of the subjective and objective symptoms of the disease; and 4, by the reduction in the mortality of the disease.

Mortality.—The mortality rate in cases of lobar pneumonia due to Type I pneumococcus not treated with serum has been shown to be from twenty-five to thirty per cent. or higher. The gross mortality rate in serum treated cases of pneumonia due to Type I pneumococcus is approximately ten per cent.

In about one third of all cases of lobar pneumonia, the Type I pneumococcus is the exciting factor; Type II is responsible for about one sixth of the total cases; and Type III is the pathogenic cause of another sixth of the cases. The remainder are caused by Group IV pneumococci. The great drawback, therefore, at present to the serum treatment of lobar pneumonia is that it is applicable only to Type I infections.

New researches.—For a number of years, efforts have been made to isolate the antibodies or immune substances from antipneumococcic sera and to produce a pure solution of potent antibodies free from the other elements of the horse serum. The researches of Felton (5), who is working under Rosenau at Harvard University, give promise of eventually placing the serum treatment of pneumonia on a more practical and efficient basis. He has succeeded in preparing refined and concentrated solutions of the antibodies contained in the various types of antipneumococcic sera, and his product is now being subjected to clinical trials in the hospitals of Boston, Chicago, New York and Pittsburgh. The results so far are fairly good, but the intravenous injection of antibody solutions from certain batches of serum produce moderate chills. Felton hopes in the near future to perfect a refined product which will have a high potency and which will produce no untoward results.

RABIES

Diagnosis.—Under the subject of rabies, let me emphasize the fact that it is a mistake to shoot or kill the suspected rabid animal. On the contrary, it should be confined and kept under observation for a period of one week. If the animal is in the incubation stage at the time of the biting, it will show symptoms of rabies and die within one week. Moreover, laboratory examination of the animal's brain fails in about three per cent to show definite lesions of rabies, and then animal inoculation tests must be made for a positive diagnosis and this requires from two to three weeks' time. Hence, if treatment is delayed for positive diagnosis, the disease may gain such headway that there will not be sufficient time for immunity to be established after the treatment is started. The safest procedure is to begin the antirabic treatment at once, without waiting for a positive diagnosis to be made from the animal.

Pasteur method.—The Pasteur treatment with some modifications has been in use since 1886 and has reduced the mortality in bitten persons from about sixteen per cent to less than one per cent. The Pasteur vaccine consists of living but attenuated virus: that is, the virulence of the virus is reduced by a slow drying process. However, some degree of paralysis has occasionally followed the antirabic treatment by the Pasteur method, and this has been attributed to true infection with the attenuated, living, rabies virus.

Semple method.—Sir David Semple (6) conducted extensive experiments in which killed, phenolized rabies virus was used to immunize rabbits, dogs, monkeys and human subjects. His researches proved that such a vaccine can be relied upon to produce a high degree of immunity and that it is a safe and an efficient rabies vaccine. Experiments (7) on animals have shown that the Semple method of vaccination against rabies gives much better protection than does the Pasteur method. During recent years, therefore the Semple method has largely superseded the older Pasteur method of treatment. Over a period of sixteen years, a total of 29,898 persons received the fourteen dose Semple treatment and the percentage of failures was only 0.7. Again, during a four year period, 2,009 Europeans were treated with the Semple vaccine at the Pasteur Institute of India and there were only 0.19 per cent of failures.

The fourteen dose Semple method of antirabic treatment consists of a 4 per cent. killed, phenolized, fixed rabies virus, and possesses distinct advantages over other methods:

1. Several investigators have shown that the spinal cord of rabbits inoculated with fixed rabies virus contains less virus than the brain, and that the virus in the cord is not so uniformly distributed as in the brain. The Semple vaccine is prepared from brain tissue and so should have greater immunizing power, gram for gram, than one prepared from spinal cords.

2. Since the virus in the brain tissue is more concentrated, also because the virus in the Semple method is killed virus and not live virus, it is possible to use relatively larger doses of the immunizing material and thus produce a protective immunity probably sooner with only fourteen doses than with the twenty-one or twenty-five doses used in other methods.

3. The entire treatment is available immediately in

a single package, for it can be stocked by the druggist; thus eliminating the necessity of waiting for subsequent doses to arrive, which often causes much anxiety to the patient.

4. Each dose is supplied diluted, ready to use.

5. Only one dose is required a day. Hence, the minimum inconvenience to the patient.

6. All doses are alike. The amount and strength of the virus is the same in each dose. This eliminates possible confusion concerning the order in which the doses should be given. Moreover, children are treated with the same dosage as adults.

7. The Semple vaccine consists of a killed virus, and such after effects as paralysis cannot occur from the vaccine.

8. Being a killed virus, it can be handled without fear on the part of either physician or patient.

It is now generally accepted, and the view is supported by experimental evidence, that the maximum degree of immunity is not developed until about two weeks after completion of antirabic treatment. The duration of immunity in man after a course of antirabic treatment is unknown, but it is generally advised that a person exposed to rabies more than six months after taking antirabic treatment should receive a new course of treatment.

SCARLET FEVER

During the past two years, there have been greater definite advances in our knowledge of the etiology and treatment of scarlet fever than in any of the other communicable diseases. Some of these advances are now sufficiently stabilized to permit of their being interpreted as important factors in the control of this disease.

How transmitted.—One important point that has been brought out in the more recent investigations is that the disease is not transmitted through the skin, for the scales during the desquamation stage do not carry the infection as was long supposed. The disease is transmitted only through air borne droplets of saliva or nasal discharges, or by contact with articles soiled with saliva, nasal secretions or the discharge from some secondary complication, such as otitis media, or through contaminated milk.

Skin tests.—Dochez (8) demonstrated that the type of hemolytic streptococcus found in the throats of scarlet fever patients was a specific and distinct type which could be differentiated from streptococci causing other forms of angina and general septic conditions. The work of Dick and Dick (9) shows that the scarlet fever streptococcus may be distinguished by growing it in broth and obtaining a soluble toxin which will give a skin test neutralizable with convalescent serum. This skin test, now known as the Dick test, is made by injecting intradermally in the forearm 0.1 c.c. of scarlet fever streptococcus toxin in correct dilution. A positive reaction occurs in twenty-four hours and is indicated by a red, inflammatory area about two centimetres in diameter. The reaction from the Dick test fades rapidly after twenty-four hours; so the test must be read twenty-four hours after it is made.

Negative reactors.—The Dick skin test seems to be reliable for detecting those persons who are susceptible to scarlet fever, but it is complicated by the fact that one negative reaction does not always seem to indicate immunity. Thus, among a series of 286 negative reactors, scarlet fever subsequently developed in eight. This phenomenon of negative reactors among susceptible persons permits of two possible explanations: 1. It may be assumed that the scarlet fever toxin has weak binding power with the tissue cells and that some injections of toxin are made in areas of skin where, for some reason, the toxin is absorbed too quickly to permit of its characteristic irritating effect being produced on the skin cells. 2. Different batches of toxin vary in their stability. Some retain their potency for a time and then suddenly deteriorate. This sudden loss of potency can be ascertained only when the toxin fails to produce a reaction in a person who previously had been shown to be Dick positive.

Immunization.—When the toxin is used for immunization, the dose employed is equal to a certain multiple of the amount of toxin used for the Dick or skin test. Hence, the dose is expressed as consisting of a certain number of skin test doses (S. T. D.) of toxin. At first, comparatively small doses were used, namely, 125, 250 and 500 S. T. D. given subcutaneously at intervals of one week. Out of 1500 children so immunized, when the Dick test was reapplied two or three months later, about fifty per cent. of them showed positive Dick reactions indicating that no immunity had developed. In another series of 900 children in whom the dose used was 125, 500 and 1,000 S. T. D., at the end of three weeks, retesting by the Dick method showed eighty per cent. negative reactors or eighty per cent. immunity. Again, in a series of 3,000 cases, doses of 1,000, 2,000 and 4,500 S. T. D. were used; and, after six weeks, fifty per cent. were still susceptible as shown by retests. Zingher in New York adopted doses of 250, 1,000, 2,000 and 3,000 S. T. D. Nesbit in his work in the public schools of Indiana used 4,000 S. T. D. for the final dose. The tendency now is to use doses of 500, 1,000, 2,500 and 5,000 S. T. D., although the Dicks advocate very much larger doses up to 20,000 S. T. D. which sometimes cause reactions simulating true scarlet fever. Hence, it would seem that the best dose for immunization had not as yet been definitely established.

Immunity.—It is not known how long the immunity will last from the toxin injections, but there is reason to believe that the immunizing treatment has produced worth while results, although improvement doubtless will be made.

However, instead of attempting to immunize exposed children with toxin, many clinicians prefer to keep them under observation for a week or two and, at the first sign of sore throat, to administer a therapeutic dose of antitoxic serum.

Serum treatment.—Scarlet fever antitoxin unquestionably marks the greatest advance in preventive medicine during the last decade. Clinical trials indicate that this new product is destined to prove as important and valuable a factor in the control of scarlet fever as is diphtheria antitoxin in the diphtheria.

Credit rightfully belongs to Dochez (10) for having first produced an antitoxic horse serum against the scarlet fever streptococcus, and for having tested its capacity to neutralize the rash locally in the skin in human cases of scarlet fever. Credit must also

be given to Dochez for having demonstrated, with the cooperation of Blake (11), the clinical value of the serum in the curative treatment of scarlet fever.

Mechanism of disease.—The clinical features of the acute stage of scarlet fever depend on two properties of the scarlet fever streptococcus. First, the property of elaborating a specific toxin; second, the property of invading tissue. The manifestations of the first property are the acute intoxication, fever, rapid pulse, leucocytosis, strawberry tongue, and the scarlet rash. The manifestations of the second are the septic complications.

The duration of the specific toxemia parallels that of the scarlet rash. When the rash has faded, the specific toxemia has been overcome. The amount of specific toxin in the patient increases each day of the disease until the rash fades; but especially the amount varies with the extent of the septic complications and is frequently extremely high in those cases with an extensive purulent rhinopharyngitis.

Indications.—All cases of the disease with a bright rash should be treated with antitoxin. In very mild cases seen on the third and fourth day, if the rash is clearly fading, antitoxin treatment may be withheld. In late cases with fading rash, slight benefit may be expected; and if the rash has faded, no benefit may be expected from antitoxin treatment.

Dose.—The rash indicates the necessity for antitoxin treatment, while the extent of the sepsis is the guide to the amount of antitoxin needed.

In all but the most severe cases, the antitoxin may be given intramuscularly into the middle anterior thigh. In extreme cases, a few hours may be gained by intravenous treatment.

The smallest or basic therapeutic dose in children or adults should be an amount that will neutralize 600,000 standard skin test doses of toxin. If the disease is moderately severe or the case is not treated until the fourth day, this dose should be doubled. If there are marked septic complications present, the basic dose should be tripled if treated by the third day; and quadrupled if treated after the third day.

Repeated dose.—If the patient remains sick twelve to twenty-four hours after treatment and the rash has not begun to fade, antitoxin treatment should be repeated. If the patient remains sick after treatment and the rash has completely faded, further antitoxin will be of no benefit.

Results.—With adequate doses, the results of antitoxin therapy are striking. Treatment should cause, within twelve to eighteen hours, a marked subjective improvement, critical fall of temperature and pulse, and fading of the rash. If the rash is old, the bright blush should disappear; but pigmentation will remain.

Little or no direct effect from antitoxin treatment may be expected on the course of septic complications. These are presumably indirectly benefited by curing the patient of the specific toxemia. Possibly the extension of septic processes may be checked by the administration of an antitoxin which also contains antibacterial bodies.

Prophylaxis.—The use of scarlet fever antitoxin for prophylaxis is not advised except in unusual circumstances: because, 1, the immunity is at best of only two to three weeks' duration; 2, the incidence of infection after exposure is only about twenty per cent.; and 3, where infection is expected, the disease can be cured on the first day by antitoxin treatment.

SMALLPOX

The United States has the unenviable distinction of reporting more smallpox during 1925 than any other country except India, namely, 43,193 cases. The largest number of cases in any one state was in California which led with 4,921. All of the six New England States together had but 102 cases, 94 of which were in Rhode Island. It is well to bear these figures in mind as a justification for the relentless application of vaccination, and the many advantages of the puncture method should appeal alike to the health officer, school physician and general practitioner.

Advantages of puncture method.—1. The virus may be wiped off immediately after vaccination; no waiting for the wound to dry before clothing touches it. 2. The least painful of any method. 3. Leaves practically no scar; hence, is an added advantage when vaccinating girls. 4. Insures greatest freedom from sore arms and infection. 5. Is the safest procedure in vaccinating infants and young children.

TETANUS

The experience gained during the World War emphasized the immense value of antitoxin in the prevention of tetanus, and demonstrated the importance of freely cutting away all dead tissue within and about extensively lacerated and contused wounds.

Types of wounds.—In every case of open wound accompanied by laceration and crushing of tissue; of punctured wounds made by iron nails, knives, sea shells and large splinters which cannot be thoroughly sterilized; bullet wounds, blank cartridge wounds or any wound into which street dirt or garden soil has been ground, an immunizing dose of tetanus antitoxin should be given and the wound at the same time should receive thorough surgical treatment. In those cases in which the wound continues to slough and show signs of infection, and in gunshot and deep-seated wounds, the dose should be repeated within a week; because the toxin which is gradually formed must be completely neutralized in order to prevent symptoms of tetanus. Moreover, tetanus spores may persist in a wound and cause "delayed tetanus" after the immunizing effect of antitoxin has worn off.

Prophylaxis.—For prophylactic purposes, the antitoxin should be administered subcutaneously, preferably in the interscapular region, so that it will be absorbed slowly and the immunity will persist for a maximum period seven to ten days. The immunizing dose now generally agreed upon is 1500 units. This dose was finally adopted by the British War Office after it had been shown that smaller doses were inadequate.

Deaths from tetanus in the state of New York from 1907 to 1925 were only one third the number which occurred eighteen years ago. This can be attributed to no other cause than the more general use of tetanus antitoxin as a preventive.

Prognosis.—The prognosis of tetanus treated without antitoxin has been exceedingly unfavorable, the mortality being estimated at seventy-four to eighty per cent. Most fatal cases occur within the first six days, and patients living to the sixth day are much

more likely to get well. The late appearing cases of tetanus, in which symptoms first occur ten or more days after the injury, give the most favorable prognosis. And cases of socalled delayed tetanus, which occur after the immunizing effect of the prophylactic dose of antitoxin has disappeared, also have a good prognosis.

When treatment with antitoxin administered by the intraspinal method was employed promptly after the recognition of tetanus symptoms, recoveries occurred in fifty to eighty per cent. of the cases. The early administration by the intraspinal route of large doses of tetanus antitoxin is essential for the successful treatment of a case of tetanus; because, after tetanus toxin up to a certain amount which constitutes the "fatal limit" has combined with the cells of the central nervous system, no amount of tetanus antitoxin can save the life of the patient.

Antitoxin treatment.—The extensive experience gained in the World War has proved that the intraspinal method of administering tetanus antitoxin should be given preference over all other methods. The intraspinal injection of antitoxin, warmed to body temperature, should be given slowly by gravity and always, if possible, under an anesthetic such as chloroform.

The technic of intraspinal administration includes making a lumbar puncture between the third and fourth lumbar vertebrae and withdrawing cerebrospinal fluid. The fluid should be allowed to flow until the cerebrospinal fluid pressure falls to normal; one drop from the needle every three to five seconds being about normal. In case of a "dry tap" which has been reported on good authority as occasionally occurring in tetanus, the intraspinal injection of antitoxin should be given cautiously.

If only a limited supply of tetanus antitoxin is immediately available, it should be given by intraspinal injections in preference to all other methods of administration.

Dose.—The dose recommended for the complete antitoxin treatment of all cases of tetanus comprises for the first day, five thousand to ten thousand units intraspinally and ten thousand units intravenously; second day, five thousand to ten thousand units intraspinally; third day, five thousand units intraspinally; and fourth day, five thousand to ten thousand units subcutaneously.

When the recommended dose and method of treatment are followed, improvement is usually manifested in forty-eight hours after the first intraspinal injection; and the improvement becomes progressive. However, the trismus and rigidity will persist after the above mentioned antitoxin treatment has been completed, but these symptoms will gradually improve without further administration of antitoxin.

Supplemental treatment.—In addition to the antitoxin treatment, proper surgical treatment for the wound should be applied and the patient placed in a quiet, darkened room with competent nursing facilities. The patient should be protected as carefully as possible from noise, excessive light, drafts, jars and other forms of irritation.

In case the wound has not already been given thorough surgical cleansing, it ought to be widely opened by free incision to cleanse it thoroughly and remove foreign substances. It is recommended that the wound be irrigated with hot peroxide of hydrogen, then swabbed out with two per cent. alcoholic solution of mercurochrome and loosely packed with gauze soaked in the same solution.

The convulsions should be controlled by sedatives, such as chloral hydrate which is well borne in tetanus cases. Many patients experience great relief from warm baths twice daily which have a decided calming effect and also tend to diminish the trismus. An adequate supply of fluid nourishment should be given, and careful attention paid to elimination by the kidneys and bowels.

(*To be concluded*)

Disease of the Lymphatic Glands Caused by Tooth Infection

A Clinical History

OLIVER T. OSBORNE, M.A., M.D., F.A.C.P.

New Haven, Conn.

Immediate history.—This patient, a woman fifty-six years of age, was first seen by me on May 12, 1924. Her immediate history was that she had discovered enlarged glands in both axillæ, the one on the left side being the larger. This gland in the left axilla was surgically removed (in another city) on April 19, 1924, less than one month before I saw her, and two separate microscopical examinations were made and the condition diagnosed as Hodgkin's disease. She was then advised to have immediate removal of several other glands, the one in the other armpit and several enlarged glands in her neck. She then saw two other physicians, and was sent to a noted blood specialist in another city who studied her general condition and the microscopic specimens of the gland that had been removed and advised strongly against operation, and stated that he thought the condition was one of lymphosarcoma, and advised the use of radium on the glands. The prognosis made in both cities was very unfavorable.

Past history.—This patient had been married only thirteen months, and had never been married before. The menopause occurred seven years ago without any disturbance of her general health. She rarely had had headaches. Had worn glasses for ten years; had slight astigmatism, slight hypermetropia, and had presbyopic lenses. When a child she had severe scarlet fever with an abscess in a gland of the neck, upper right side, the scar of which is still present. She had typhoid fever at sixteen years of age. She had never had any other serious condition, even colds or tonsillitis.

She noticed the enlarged gland in the left axilla only two weeks before it was removed, namely, about six weeks before I first saw her. The wound healed nicely, and there were no indurations or swellings in that region. The enlarged gland in the right axilla she says is smaller than it was a few weeks ago. The gland removed from the left axilla was a little larger than a plum.

The family history is entirely negative as bearing any relation to her condition.

Present condition.—She has not lost weight. Her appetite is fine; no indigestion, nausea, or vomiting. Bowel action is normal without medicine. She eats meat once a day and a normal amount of carbohydrates and fats, eats considerable butter, a normal amount of salt; dislikes sweets, likes acids; takes one cup of coffee and two cups of tea a day. She sleeps well. Nocturia once or twice. Rather frequent urination in the morning, but normal in the afternoon. Perspiration is slightly subnormal. She says she feels perfectly well, if she was not so terribly frightened. Her weight is normal, and she is well nourished.

Examination.—The tongue is slightly coated. Tonsils and throat are normal. Teeth look fine. About two months ago she had one tooth extracted which was not dead, and there was no pus in the tooth socket, but it "just bothered her a little." Her hair is fine and does not fall out. Hands tend to be dry. One finger of the left hand shows a slight gouty condition. She gives no history of rheumatism or joint pains. Pupils react normally. Patellar reflexes are normal. There is no edema; no soreness of the bones; no eruptions, and she never had any eruptions. The lungs are normal; heart sounds are normal, not strong, no murmurs, normal size. The abdomen is negative. Spleen and liver apparently normal. Pelvis is negative. No glands found in the abdomen; no enlarged glands in the groins. The pulse is 76, weak and regular. The blood pressure is 102 systolic; 68 diastolic.

In the right axilla there is a gland which is very slightly enlarged. In the left side of the neck is a small gland or nodule, not larger than a large pea. In the right neck, rather low down, is a small gland which she says varies in size from time to time and has been present for five years or more. At the present time this is about the size of a small hazelnut. She says when this gland swells there is a small nodule occurs simultaneously just back of the mastoid process in the occipital region. Also a gland enlarges towards the shoulder just above the clavicle on that side.

Examination of the urine was negative. Red blood corpuscles were 3,912,000; hemoglobin 60 per cent.; 10,000 white blood corpuscles; polymorphonuclears 47 per cent.; large and small lymphocytes 48 per cent.; eosinophiles 5 per cent. In other words, there was a moderate anemia and a relative lymphocytosis.

Examination of the tonsils, nose, nasopharynx, and sinuses was negative and showed no infection. Examination of the feces was negative; normal digestion; no parasites. X rays and examination of the teeth showed every tooth to be alive and normal, except the upper right lateral which shows infection at the apex. X ray pictures of the chest were negative. On May 23, 1924, this tooth was extracted and laboratory culture showed Staphylococcus aureus and Streptococcus nonhemolyticus.

In view of the serious diagnoses and prognoses that had been given by good men and specialists in two different cities, I did not give her much encouragement, but told her that her condition could be due entirely to focal infection proceeding from this tooth and perhaps from the tooth that had been previously extracted.

TREATMENT

She was put upon a liberal protein diet and given red bonemarrow and spleen tablets.

On May 29, 1924, the gland in the right axilla had all but disappeared, in fact, it was apparently normal in size. In the left axilla there was no gland to be felt, and no induration; this was where the gland had been removed. The small gland in the left neck was just palpable. The gland in the right neck remained about the same size. The blood count at this date, May 29th, showed the red cells to have increased to 5,184,000; hemoglobin 80 per cent.; total white count 12,800; polymorphonuclears 45 per cent.; large and small lymphocytes 52 per cent.; eosinophiles 3 per cent., a continued moderate relative lymphocytosis.

At this date, besides the treatment outlined above, she was given one grain of thyroid extract a day.

July 8, 1924: Condition had continued to improve. She had gained several pounds in weight. There were no enlarged glands to be found anywhere except that small nodule in the right side of the neck, the one she had had for so many years. Treatment was temporarily stopped.

September 25, 1924: She complained of feeling a little weak. Blood examination shows 4,152,000 red corpuscles; 75 per cent. hemoglobin; 7,300 leucocytes; polymorphonuclears 38 per cent.; large and small lymphocytes 54 per cent.; eosinophiles 4 per cent. and 4 per cent. myelocytes. The blood pressure was still low, 105 systolic; 65 diastolic. She was given tonics, including iron, and intermittently small doses of thyroid extract, which always stimulated her and seemed to improve her general condition.

January 9, 1925: Throughout the fall of 1924 treatment kept her pretty well, but not strong and sturdy, and there were frequent enlargements of that old gland in the right neck, with the occipital gland enlargement and enlargement of the gland toward the shoulder region above the clavicle on the right side; never any other gland enlargements. Occasionally some little shoulder and knee pains occurred. The blood count at this date showed 4,664,000 red cells; hemoglobin 80 per cent.; white cells 12,200; polymorphonuclears 42 per cent.; large and small lymphocytes 56 per cent.; eosinophiles 1 per cent.; basophiles 1 per cent., still this relative lymphocytosis. Another blood count was made on February 9th, which showed practically the same condition as the last, namely, increased total leucocytes and relatively increased lymphocytes.

May 11, 1925: The blood count at this date was: red corpuscles 4,588,000; hemoglobin 90 per cent.; total leucocytes 15,800; polymorphonuclears 46 per cent.; large and small lymphocytes 53 per cent.; eosinophiles 1 per cent.

I then decided that this gland which was always evident and at times would enlarge and cause other glands to enlarge (at least I so interpreted it), should

be removed. Dr. William F. Verdi, of New Haven, concurred in this opinion, and removed the gland on May 13, 1925. Laboratory examination by Dean Milton Winternitz, of the Yale Medical School, without knowing anything of the history of the case, caused him to state that it looked like an early Hodgkin's disease; that it was not lymphosarcoma.

October 8, 1925: During the summer the occipital gland and the gland at the right side of the neck toward the shoulder entirely disappeared as far as palpable evidence showed. The blood count at this date showed 5,680,000 red corpuscles; hemoglobin 80 per cent.; total white corpuscles 8,800; polymorphonuclears 55 per cent.; large and small lymphocytes 45 per cent.; in other words, the blood count was practically normal.

March 8, 1926: The blood count showed 4,424,000 red corpuscles; hemoglobin 70 per cent.; total leucocytes 9,100; polymorphonuclears 67 per cent.; lymphocytes 32 per cent.; eosinophiles 1 per cent., and all cells normal.

Present condition.—This patient, now fifty-eight years of age, has occasionally some slight indisposition, but retains her weight, has no enlarged glands, and is really very well. The blood pressure is always a little too low, but she is active, and able to do all ordinary things.

COMMENT

It would seem there could be no better proof than this case to show what tooth infection and an infected gland can do. Her socalled Hodgkin's disease did not progress, lymphosarcoma did not develop, and at the present time she has not an abnormal enlarged gland anywhere discoverable, and her blood count has become practically normal, with a tendency towards slight anemia if she does not occasionally take some extra iron or a little thyroid.

This patient has asked me to publish an account of her illness that perhaps someone may not be condemned to dangerous operations or to hopeless prognosis when possibly focal infection is at the bottom of the trouble. Certainly, the seriousness of focal infection, especially of the teeth, cannot be too much emphasized.

Ureteral Obstruction as Etiological Factor in Renal Calculus*

A. RAVICH, M.A., M.D.
Brooklyn, N. Y.

In view of the high state of efficiency that the specialty of urology has attained in its diagnostic capabilities, it is surprising how relatively unfamiliar this fact still remains to the average physician. Every practitioner seems to be on the alert regarding such conditions as appendicitis, cholecystitis, cholelithiasis, gastric ulcer, and other similar conditions, even though in many instances, in spite of all the clinical data at his disposal, the diagnosis cannot be arrived at with absolute certainty.

Numerous instances occur daily of operations performed and normal appendices, gallbladders, tubes, and ovaries removed; of stomachs and even kidneys opened or removed without presenting any definite pathological condition. The surgeon, however, is not the only one at fault; the gastroenterologist who treats these poor, much abused stomachs for years without giving the patient the desired relief is just as faulty. Too much attention being given to a one-sided biased history, the patient is put through numerous complicated examinations at the latter's great expense and inconvenience. When a simple but careful microscopic analysis of urine is needed, which requires a few moments and no special paraphernalia or knowledge, many of us consider it beneath our dignity to do it ourselves or unworthy of the time it takes. Instead, we often depend upon an inexperienced and disinterested layman for the accuracy of a report which necessarily plays a very important rôle in the diagnosis. On the other hand, even thoroughly reliable reports very frequently receive but hasty and inadequate attention from the physician in charge of the case. How often does one come across instances in which a careful uranalysis will completely reverse the previous opinion of a case in question, even to the extent of withholding consent to operative interference.

In the meantime, owing to incomplete study, many a patient is operated upon for some chronic condition and an apparently normal organ is removed upon the supposition that it is chronically inflamed. If the same symptoms persist after operation, the blame is then attributed either to the patient's nerves, another organ or to socalled "postoperative adhesions." The cases of renal and ureteral calculus and obstructions that have had previous appendectomies performed without relief are so numerous that one becomes somewhat skeptical at times of the existence of chronic appendicitis *per se*. Why do such errors in judgment and diagnosis still continue? It is probably not entirely the fault of the doctor. It would be a simple matter to discover the disturbing factor if we were not possessed of so many reflex and sympathetic bypaths. Such a complicated state of affairs, therefore, should make us doubly cautious. To make a diagnosis of fracture without corroboration by the x ray would now be considered poor judgment. So, too, in the diagnosis of syphilis, no one would now make a positive diagnosis of this disease without bringing to his aid such positive laboratory examinations as the dark field and Wassermann tests. Still, we have all witnessed operations performed for the relief of indefinite symptoms which later upon more careful examination were found to be due to renal or ureteral calculus. This remains prevalent in spite of having at our command such a positive diagnostic combination as urinalysis, radiography, cystoscopy, and pyelography. If one or more of these be utilized in atypical abdominal ailments many an unnecessary operation can be avoided.

Under the old presumption that diet was the pre-

*Read before the Brooklyn Urological Association March 10, 1925.

dominant factor in the formation and growth of renal and ureteral calculi, numerous diet lists had been elaborated and patients were deprived of almost every conceivable kind of food without any effect on the growth or recurrence of these stones. After removal of these calculi, he would be warned against imbibing any liquid save distilled water, and eating any food that was not cooked in such fluid. The

FIG. 1.—Case of right ureteral calculus with hydronephrosis and multiple strictures of the ureter. C shows location of calculus.

patient would be so bewildered by the long array of foods to avoid that he would naturally cheat a little, either knowingly or unknowingly. When such infractions were discovered, we would throw up our hands in horror and blame it all on the wrongdoings of the poor patient. As a matter of personal belief, I cannot recall a single instance in which a reasonable normal nonirritating diet *per se* played any part in the formation or recurrence of calculi, nor have I seen any prevented by the most rigid diets. L. D. Keyser of the Mayo Foundation (1) after an exhaustive experimental study comes to the conclusion that diet alone plays no part in the formation of urinary calculus, and that oxalurias, phosphaturias and excessive uric acid excretion are more of endogenous than of exogenous origin. In the first two conditions as well as in gout, contrary to popular opinion, one rarely finds an accompanying calculus deposition.

This being the case we must look elsewhere for the etiology of renal stones. In accordance with the views first expounded by Dr. Guy L. Hunner, it seems that we are now closer to the solution of this mystery than ever before. He contends that ureteral obstruction such as stricture usually precedes and is an important factor in the formation of calculi. Given a patient with a lithic diathesis plus a chronic irritation of the mucous membrane of the upper urinary apparatus by obstruction somewhere along the urinary tract, the end result will be a renal or ureteral calculus. One can very logically refer to the many cases of pyelitis, ureteral strictures, etc., without calculi. So, too, there is such a multiplicity of hypertrophied prostates, enlarged median bars and other obstructive lesions at the neck of the bladder associated with cystitis, yet in only relatively few of these do vesical stones develop.

Why then should mechanical obstruction play such an important rôle in the formation of calculi? In answer to this, it is well known that calculus in female bladders is almost unheard of except when it grows around sutures that have penetrated the vesical mucosa or around foreign bodies. Lithic diathesis is apparently about equally divided among males and females; for where both are subject to similar obstructions as is seen in the kidney and ureter which are anatomically similar in both sexes, the incidence of calculus formation is evenly distributed between the two. Vesical calculi in male bladders, however, are of common occurrence because we have that all important, yes, one might say, the most essential factor in stone formation, viz., obstruction to the urinary outflow. Urinary stasis and the inflammation of the mucous membrane thereby produced, will in some unknown way cause a disturbance in the normal colloidal mechanism of the urine with a consequent crystallization and fusion of the urinary salts. A urinary apparatus, be it kidney or bladder, that empties itself properly at all times, does not form calculi. Granting the above assumption then, it would be fallacious to open up a kidney

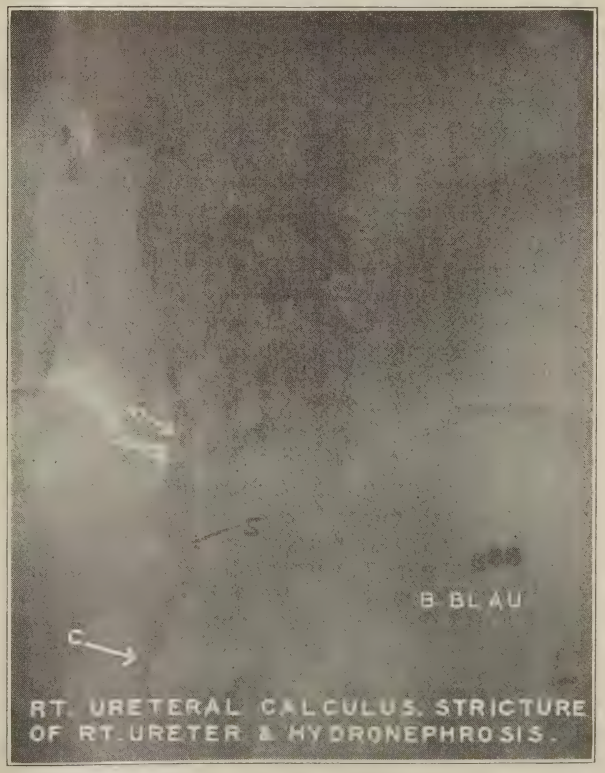

FIG. 2.—Case of right ureteral calculus with hydronephrosis and multiple strictures of the ureter.

or ureter for the removal of a stone without at the same time or subsequently thereto clearing up the obstruction in the urinary passage that played such an important part in the original pathology. This is probably the reason why statistics report such a large proportion of recurrences after the spontaneous or operative removal of urinary calculi. Recurrence of

calculi can usually be presented by occasional but repeated dilatation of the ureteral obstructions that are found present in these cases.

In doing a partial or complete nephrotomy, sutures must be placed into the renal substance to check hemorrhage. This procedure produces a four fold injury. First, it brings in such irritating foreign bodies as sutures and blood clots; secondly, it constricts some

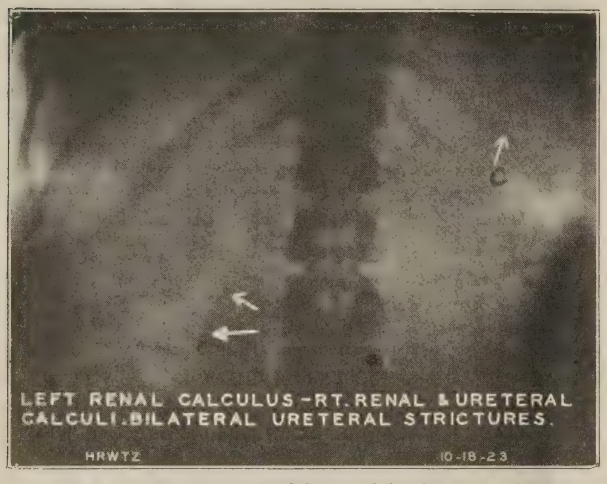

FIG. 3.—Shows the two calculi impacted in the upper right ureter and the pyeloureterogram on the left side shows the stricture of the upper portion of the left ureter which is the apparent etiological factor in the formation of the left renal calculus.

portions of the kidney tubules causing stasis of the urinary flow in the part so treated; thirdly, it creates microscopic or macroscopic pools or lakes in which the urine stagnates, and fourthly, it produces some unknown physiochemical reaction or disturbance which conduces to further crystallization of the urinary salts with the resultant recurrence of renal calculi. This is the reason that pyelotomy where possible has become the operation of choice for the removal of renal calculi, and why so many complete nephrotomies have been followed by the formation of large stones, which subsequently required nephrectomy. Pyelotomy, however, when feasible, does a minimum amount of damage to the kidney, for if properly performed it does not add to the urinary stasis in the kidney. The only drawback to the operation is that many surgeons still fail to correct the urinary obstruction which in accordance with the above reasoning is the essential predisposing cause for the formation of the stone. These cases must be followed up after operation until the ureteral obstruction and the postoperative infection are cleared up.

If there were no obstructions in the ureter the passage of the ordinary sized stone should be a very simple matter and in the course of one short attack of colic the calculus should be shot out into the bladder. Clinically, however, we have all frequently observed the difficulty with which even tiny calculi are expelled from the ureter and how numerous and severe the attacks necessary to accomplish this result. It is a common occurrence to see stones no larger than a B. B. shot require months of persistent cystoscopic treatment before being passed out into the bladder.

The following cases are cited to illustrate the dire results of inadequate study:

CASE I.—A physician of fifty having had pain in the right iliac and right lumbar regions for ten years, had had an appendectomy performed without relief of symptoms. X ray examinations for several years subsequently were apparently negative. Somewhat later a tiny calculus was discovered in the right kidney. Several cystoscopies and pyelography failed to dislodge the stone. A nephrotomy was accordingly performed by a recognized surgeon but in spite of a painstaking search the calculus could not be found. Less than a year later the patient was again radiographed and instead of the tiny calculus present before operation he now had a good sized stone. This had continued to grow until at the present time he has a calculus the size of a plum. The patient still had more or less constant dull backache with occasional attacks of sharp pain in the right iliac region. It is reasonable to suppose that if this man's ureter were dilated in the first place, the calculus might have remained practically stationary in size and with continued manipulations might have passed out into the bladder. Furthermore, even after the nephrotomy, had adequate urinary drainage and disinfection been provided by correction of the ureteral obstruction the calculus, in all probability, might not have grown so large in such a short time. Having had such bitter experience, the patient loathes to have any other operative work performed. During the past year he

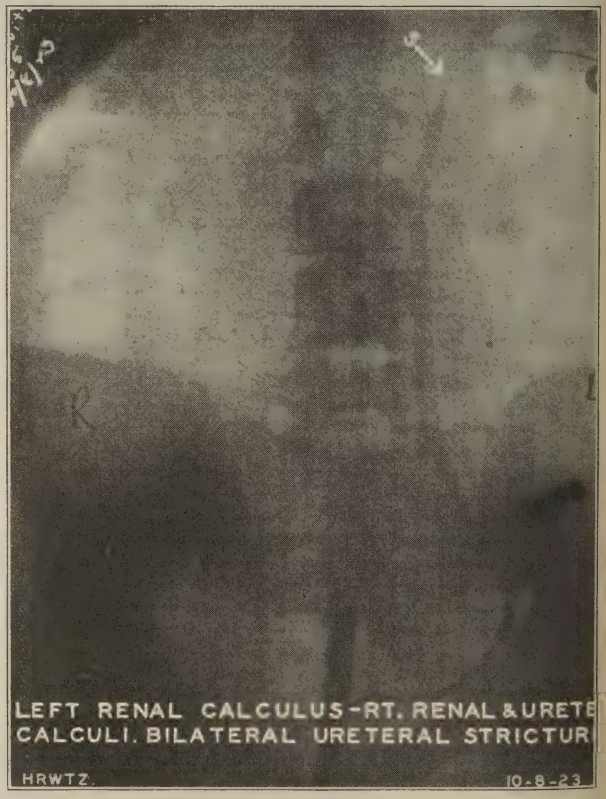

FIG. 4.—Shows the two calculi impacted in the upper right ureter and the pyeloureterogram on the left side shows the stricture of the upper portion of the left ureter.

has obtained considerable relief by occasional ureteral dilatations.

CASE II.—Another case of hasty and careless surgical interference is that of a woman who came into the hospital with typical attacks and history of right

renal colic. Radiographs showed two fairly large but very indefinite shadows in the lower calyx of the right kidney. Microscopic blood was found in the urine. A pyelogram was made and was not considered particularly abnormal. A ureterogram was not done. On

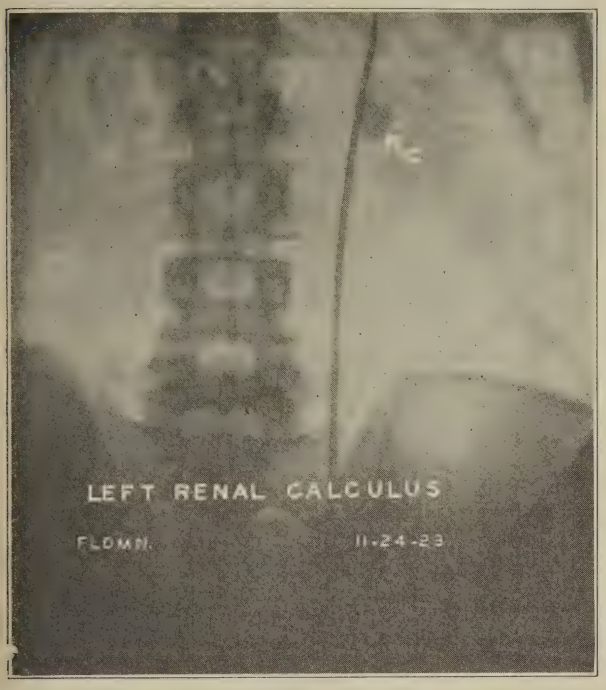

FIG. 5.—Shows the calculus in the renal pelvis and the pyeloureterogram shows the strictures which accompany this condition.

the strength of the urinary findings, symptoms and the indefinite shadows reported by the radiologist, a diagnosis of renal calculi was made. The surgeon performed a partial nephrotomy but in spite of a thorough search the supposed calculi were not found. A more careful review of the preoperative findings and radiograms proved this to be a case of ureteral stricture which could have easily been corrected by nonoperative means.

The number of patients treated or operated upon for divers conditions, that, after more thorough investigation are found to be due to stone, must be enormous. If the poor patient is unfortunate enough to have a calculus in the right ureter, he is indeed lucky if he comes out of the fray minus a mere appendix or gallbladder. Those others who are just sentenced to the strict dieting that follows the diagnosis of gastric or duodenal ulcer are comparatively fortunate.

The latter brings to mind an intelligent woman, who for years had been treated medically for gastric ulcer by some of our foremost gastroenterologists. Gastric contents and numerous gastrointestinal radiographs were examined with great care. Even urines had been examined; with what pains it is difficult to state. At any rate no significance had been attached to the pus, erythrocytes and bacteria which were found in the urine. A careful cystoscopy, x ray and pyelography established the presence of a medium sized obstructing calculus in the lower right ureter with a marked hydroureter and a functionless pyonephrotic kidney sac which was removed. Had this patient been radiographed without bismuth and had her urine been examined as assiduously as her gastric contents, she probably would still have had the two kidneys with which Nature had endowed her.

CASE III.—Another patient who unluckily fell into the ever increasing army of appendectomized individuals is a young man of thirty-three who had a sudden attack of severe colic over the appendicular region which awakened him from a sound sleep. After three such attacks, and in spite of the history of microscopic hematuria for six months and the pleading of the patient for an x ray examination, appendectomy was performed. Within a short time the colic recurred and a diagnosis of "adhesions" was made. A urological examination revealed a microscopic hematuria, a small calculus about the size of a pea in the lower right ureter, a hydronephrosis and multiple strictures of the ureter, as shown in Figs. 1 and 2.

CASE IV.—A poor unfortunate woman of twenty-eight has had more than her share of misfortune. For five and a half years she had had bilateral lumbar pain. For a sudden attack of abdominal distention and colic, one and a half years ago, she was operated upon for hemorrhagic pancreatitis and her pancreas drained. About nine months later, for a sudden attack of right upper abdominal colic, she had a so-called chronic gallbladder removed. Not having anything else of surgical importance to remove, and because of continued suffering, she submitted to a careful urological and radiographic examination. This revealed a microscopic hematuria, a small cal-

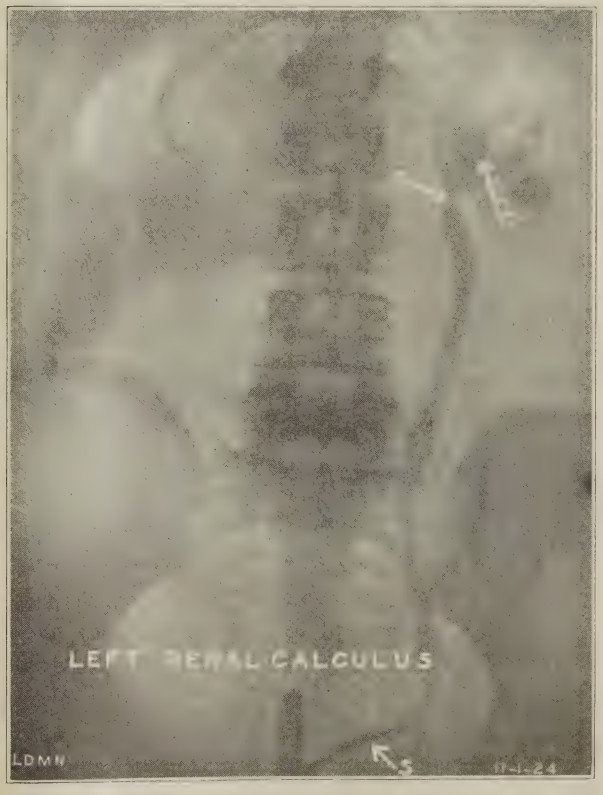

FIG. 6.—Shows the calculus in the renal pelvis and the pyeloureterogram shows the strictures which accompany this condition.

culus in the right renal pelvis, a very tight stricture and small calculus in the upper right ureter which remained stationary in spite of several ureter catheterizations, and a fairly large calculus the size of a small hazel nut in the upper calyx of the left kidney. Although one cannot say that the urinary condition

was originally the cause of all her symptoms, the evidence is very much in favor of such a supposition. (Figs. 3 and 4.)

Case V.—Lumbago is another ailment which is blamed for many a case of renal calculus and in point of frequency of error, it may easily claim to be a close second to appendicitis. A striking example of this occurred in a woman of forty-four who for many years had been treated for lumbago. The hematuria which she had had fifteen years before never received serious consideration. For two months prior to admission to the hospital she had had a persistent hematuria which was found coming from the right kidney and was checked only after several ureteral dilatations. Large multiple calculi were found in both kidneys and a fairly large irregular calculus in the lower left ureter. In view of the very poor phthalein output and the very bad cardiac condition, she was deemed too hazardous a risk for immediate operation.

Case VI.—Another patient twenty-eight years old had been suffering for nine years from pain in the lower left abdomen. She was finally advised to undergo an operation for chronic left ovarian disease. Examination revealed a calculus the size of a hazel nut in the left renal pelvis with multiple strictures of the left ureter. (Figs. 5 and 6.)

The socalled renorenal reflex has remained an accepted fact for years. Many a time we were surprised to find the calculus on the side which gave no symptoms and everything supposedly negative on the side of the colic. In the light of our present knowledge of kidney and ureter pathology, it is doubtful whether such a condition exists.

Numerous instances of this condition might be cited, but space will not permit. The object of this contribution is to stimulate a more active interest in the brilliant discoveries that have been made during the past decade in the realm of urology with the hope that a more extensive and careful use be made of that accurate and harmess triad—uranalysis, radiography and cystoscopy in the diagnosis and treatment of all atypical abdominal conditions.

CONCLUSIONS

1. A careful microscopic examination of a freshly and properly obtained specimen of urine is of paramount importance.
2. A combination of radiography, cystoscopy and pyeloureterography should be employed more often to establish a diagnosis in atypical abdominal conditions.
3. Diet *per se* apparently bears little if any influence on the formation of urinary calculi.
4. Obstruction somewhere along the urinary tract is probably the most important single factor in the causation of urinary lithiasis and its retarded passage through the ureter.
5. The large percentage of recurrent calculi is due to failure to correct the urinary stasis.
6. Wherever possible pyelotomy is preferable to nephrotomy in the removal of renal calculi.
7. The great majority of ureteral calculi can be made to pass without operative interference.

Congenitally Misplaced (Pelvic) Kidney*

A. H. FINEMAN, M.D.
New York

Cases of congenitally misplaced kidney are rare, particularly those in which the organ is situated in the true pelvis. Relatively few instances of such an abnormal position have been recorded in the literature. Among the more recent reports are those by Bunce (1), Kasper (2), Anderson (3) and Bryan (4). Because of the rarity of this condition and the interesting anomalous findings that it presents, the following case is herein reported.

Case.—M. J., male, aged twenty-seven, was admitted to the Metropolitan Hospital on December 8, 1925, complaining of weakness and loss of weight for two years and cough with occasional epistaxis for one year. He had fever on and off, with moderate sweats. Six months previously, he was admitted to another hospital with a diagnosis of pneumonia and was confined to that institution until November 8, 1925. Since then he has suffered with cough and nose bleeds and has been getting progressively worse. No other symptoms were present. Dysuria, hematuria and frequent micturition were absent. No pain in the abdomen was experienced. The family history was negative.

Physical examination showed a thin, poorly nourished young man, much underweight (108 pounds) and chronically ill. Dullness, bronchovesicular breathing and moist râles were present over the upper lobe of each lung. The heart sounds were normal. The abdomen was flat and on palpation presented no tenderness, rigidity or masses. The liver, spleen and kidneys were not felt. A clinical diagnosis of bilateral pulmonary tuberculosis was made.

Uranalysis showed a heavy trace of albumin, many hyaline casts, a moderate amount of pus and epithelial cells and an occasional red blood cell. The blood chemistry was normal. The patient had an irregular fever and rapid pulse, became progressively weaker and died on January 10, 1926, about one month after his admission to the hospital.

When the abdomen was opened, two months later, the interesting anomaly was discovered. The right kidney was normal in size, shape and position, possessing an accessory inferior polar artery. The right ureter was eight inches long. The adrenal gland was in its normal position. (Fig. 1.)

The left kidney was found as a retroperitoneal organ in the true pelvis, the upper third overlapping

*From the Department of Anatomy, Columbia University.

the promontory of the sacrum and the pelvic inlet. The organ was firmly fixed and bound down by peritoneum. This kidney was slightly larger than the other and consisted of two portions, a small upper part, mushroomlike in form, and a large flat lower part. (Fig. 1.) The upper portion could be partially rotated forward and to the left, thereby exposing the hilum of the kidney. The renal artery was found behind the upper part of the kidney, arising from the right common iliac and passing downward and to the left to divide into three branches. The renal vein emerged from the hilum, passing upward and to the right, to enter the left common iliac vein. The pelvis of the ureter was situated between the inferior margin of the upper portion and the front of the lower portion of the kidney; the ureter passing in front of and then behind the lower pole to terminate finally in the bladder. The left ureter was less than half the length of the right, being only three and one half inches in extent. An accessory artery was found on the front of the kidney, arising a short distance above the bifurcation of the abdominal aorta and coursing vertically downward, distributing a small branch to the upper portion. The adrenal gland was not in relation to the kidney. Frozen sections of lungs and kidneys failed to demonstrate the existence of giant cells, but considerable round cell filtration was present.

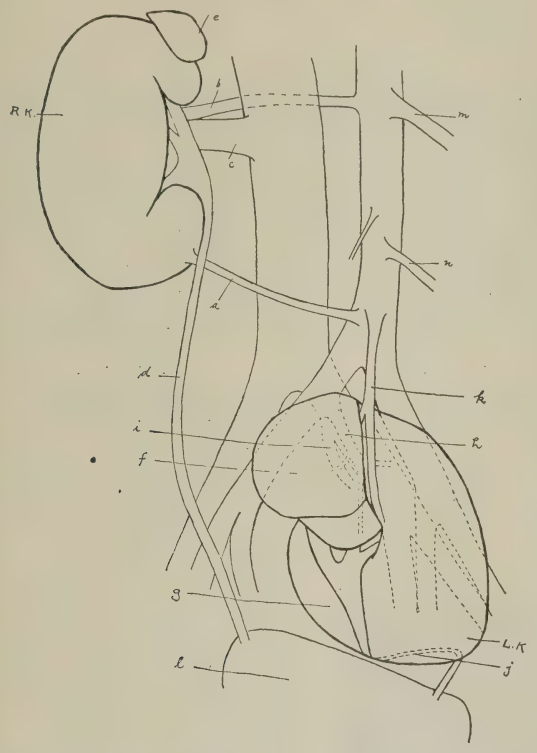

FIG. 1.—Diagram illustrating the relative position of the kidneys: Right kidney, R.K., normally situated, with an inferior polar artery, a; renal artery, b; renal vein, c; ureter, d; and adrenal, e. Left kidney, L.K., situated in the pelvis, overlapping the promontory and pelvic inlet. Upper portion, f, of left kidney; lower portion, g; left renal artery, h; renal vein, i; ureter, j; accessory artery, k; bladder, l; superior mesenteric artery, m; inferior mesenteric artery, n.

COMMENT

A congenitally misplaced kidney is rarely diagnosed during life because it seldom gives rise to symptoms referable to the genitourinary tract and if palpated in the course of a physical examination is usually mistaken for a neoplasm. According to Squier (5) cases are on record where even at operation such anomalies have been misjudged for new growths and removed unnecessarily. In our case, when the abdomen was first opened, the mass found in the pelvis was thought to be a retroperitoneal tumor and only after removal of the serous covering was it identified as an abnormally placed kidney. From the anomalous origin of the renal vessels and the existence of a shortened ureter, it is quite apparent that this abnormality is a congenital one, due to a premature arrest in the ascent of the kidney and differing embryologically from the condition in which the organ is ptosed or dropped, in which instance the blood supply is relatively normal. Mention should be made of the fact that the adrenal gland does not, as a rule, participate in congenital renal misplacements.

In our case, the only finding that might have aroused suspicion of a renal anomaly was the presence of pus in the urine. In cases of pyuria without urinary symptoms, the possibility of renal malformation or misplacement should be considered.

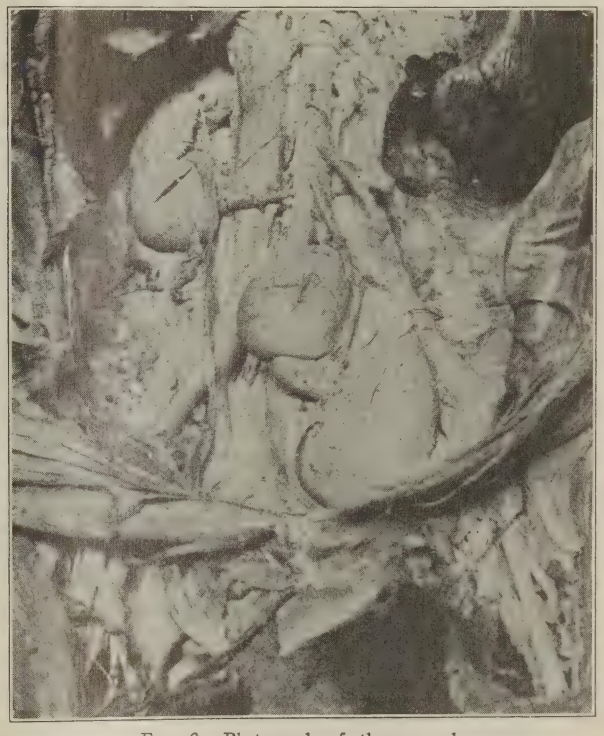

FIG. 2.—Photograph of the anomaly.

Dermatitis from Adhesive Plaster

With Report of Cases

DOUGLASS W. MONTGOMERY, M.D.
and GEORGE D. CULVER, M.D.
San Francisco, California.

Recently W. P. Brown has reported an interesting case of sensitiveness to adhesive plaster (1). And shortly afterwards a patient come to the office showing a marked example of the same trouble.

A woman forty-five years of age consulted us August 6, 1925, on account of a streptococcic dermatitis. Some weeks previously she had been operated upon for a nevus situated on the posterior aspect of the left side of the chest, and when she came to us the scar was covered with an impetiginous crust, and the skin around it was blazing red. The sensations complained of were a mixture of pain and itching. Besides this she had an erythematous eczema on the base of the neck, and to show how easily one may be led astray by imagined local causes we at first thought that this might be due to a black fur collar she was wearing. When, however, we heard that she had worn it for three years without any trouble arising from it previously we changed our mind.

On the patient's second visit to the office the intense redness about the wound had subsided, and the dermatitis occasioned by the adhesive bands came out with startling clearness as a sunburst shown in the photograph, and one of the interesting features was that it had now been four weeks since any plaster had been applied. It was a surprise to us to learn that the effect of the irritant could endure so long. (Fig. 1.)

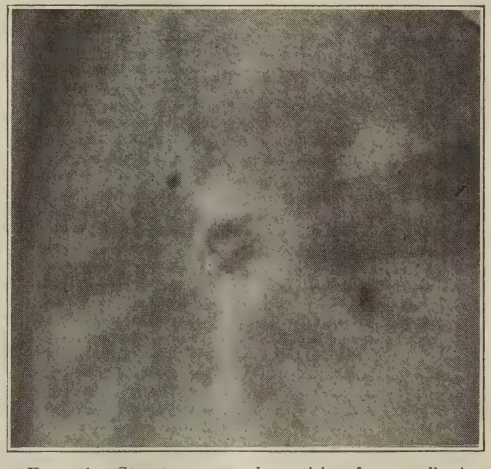

Fig. 1.—Streptococcus dermatitis from adhesive plaster which was used to treat a nevus on the left side of the patient's chest.

How serious this sensitiveness may be, was shown in the case of a friend of ours, a physician in San Francisco, who is extremely sensitive to adhesive plaster, and to turpentine, and an experience he had shows how important a knowledge of this may be to a medical man. On being operated upon for appendicitis he warned his two surgical friends of this sensitiveness.

The surgeon who operated is distinguished by having an enormous hand, and his wound aperture was correspondingly large. I suppose that both the operator and his coadjutor thought that the warnings regarding adhesive plaster were not to be taken too seriously. In closing the wound they had used adhesive plaster very extensively, which aroused a blazing dermatitis, and the reaction had extended also even into the ample wound, causing the most excruciating agony.

Another interesting experience in the same line concerned a man forty-three years of age who was sent to us on account of an eczema, papular of the hands and forearms, erythematous of the face. He said that it had begun seven weeks previously while cleaning the woodwork in railway cars, in which he used turpentine. He said that he had stopped work for two weeks and the eczema had improved, to again become worse on resuming work. While examining him we noticed a bandlike dermatitis on the forearm, which he said was where a strip of adhesive plaster had been applied to support a bandage.

Obviously, the adhesive plaster had caused the bandlike dermatitis, and presumably because of the resin contained in it, and as resin is turpentine devoid of its volatile constituents it was only reasonable to infer that the turpentine employed in cleaning the cars would also aggravate the patient's eczematous skin. Such an opinion was therefore given to the industrial commission.

Extreme susceptibility to adhesive plaster must be, as Dr. Brown has found, rare. In our radium work we use it a great deal and abundantly, in fixing the radium plaques over the lesions treated, and we never have met with a case where its use has been absolutely precluded. In one instance we had to vary from day to day the situation of the adhesive bands, and in another the plaster caused minute folliculitis.

According to a report by the *Journal of the American Medical Association* the methods of making adhesive plasters are more or less secret, but it seems that they all consist of a mixture of rubber, resins, and waxes, with an absorbent powder, such as oxide of zinc, orris root or starch, as a filler.

CONCLUSIONS

1. Adhesive plaster may cause a severe and prolonged dermatitis, which often by its geometrical shape indicates its origin.

2. The dermatitis which is produced by the adhesive plaster is caused by the resin or turpentine which it contains.

The Serology of General Paresis in the Malaria Treated Cases

ARMANDO FERRARO, M.D.
and THEODORE C. C. FONG, M.D.
St. Elizabeth's Hospital, Washington, D. C.

(*Continued from page* 566)

Table VIII shows the serological modification within thirty-six months after malaria treatment. At this period astonishing changes are seen in the Wassermann reaction in both blood and cerebrospinal fluid; twenty of the twenty-three cases show negative blood Wassermann and sixteen negative spinal fluid Wassermann. The colloidal gold appears improved in almost all the cases and, in two of them reported in the table, the curve is entirely negative. In a few cases the mastic reaction has also been performed and the great majority of the cases show an improvement in the curve.

The oldest patient in our series was inoculated with malaria in December, 1922, and the last spinal fluid was taken three months ago (forty months after the inoculation). His serology is reported in Table IX and it may be seen that the reactions have to be considered as practically normal and not differing very much from the results obtained in some of the cases thirty-six months from treatment.

In order to show the gradual improvement in the serology of paretic cases following the malaria treatment, we have collected in the following tables results of detailed examinations of the cerebrospinal fluid of two cases. In these, nine and eleven spinal punctures were performed at intervals of several months. The gradual improvement starting soon after the malaria treatment can easily be followed.

The influence of repeated spinal puncture on the serological results, and especially on the albumin and cell content, might be questioned. This gave rise to the experimental investigations of Weigeldt and Ropke, who, after repeated spinal puncture at short intervals of time, found that the chemical and morphological composition of the cerebrospinal fluid undergoes some modifications. These conclusions, at least those concerning the serological formula of general paresis, have not been confirmed by Kaltenbach (37), who, after repeated spinal puncture at short intervals of time, could detect no appreciable influence on the previous results.

A question of great interest, especially from the viewpoint of the mechanism of the action of malaria on the pathology of general paresis, is whether any relationship between the temperature, the number of chills and the corresponding improvement exists. Table XII shows the relationship between temperature and serological improvement and Table XIII the relationship between the number of paroxysms and the serological improvement.

We can say, in the beginning, that no parallelism exists between the maximum temperature of the paroxysms and the serological improvement, as with the increase of the temperature the proportions between the unchanged and the improved cases scarcely change; for instance, while, with a maximum temperature of 105°, the number of improved cases are thirteen against ten unimproved, the proportions are six to five with a temperature of two more degrees (107° F.).

But, if we take into consideration the average of the improved cases compared with the average of the number of paroxysms, we soon find that a relationship seems to exist between the number of paroxysms and the percentage of improved cases. With an average of six paroxysms, the average is four improved against fourteen unimproved; the number of improved cases gradually increases, reaching twenty-six improved against eighteen unimproved when the average number of chills is eighteen. A few cases had from nineteen to twenty-four paroxysms, and even in this small number it may be seen that the proportion between improved and unimproved cases was greater.

The next problem is the relationship between the serological and the clinical improvement. In order to answer this question, we must take into consideration, first, the percentage of all the cases serologically improved, and then analyze separately the results obtained in relation to the different periods of time that have elapsed since date of treatment. Forty-four out of eighty-six, i. e., 51.16 per cent. of the cases are serologically improved. But if the percentage is calculated separately as stated above, we easily see how the percentage gradually increases in proportion to the period of time that has elapsed from the date of malaria treatment. For this purpose, the cases have been divided into four groups and, in the first group, the cases of less than a month's duration after the malaria inoculation have not been taken into consideration. The percentage of the improved cases relative to the period of time is as follows:

Within 6 months: 20 cases—
Serologically improved 3: 15 per cent.
Serologically unchanged 17: 85 per cent.

Within 12 months: 22 cases—
Serologically improved 8: 36.32 per cent.
Serologically unchanged 14: 63.68 per cent.

Within 24 months: 15 cases—
Serologically improved 8: 52.8 per cent.
Serologically unchanged 7: 47.2 per cent.

Within 36 months: 39 cases—
Serologically improved 25: 85 per cent.
Serologically unchanged 4: 15 per cent.

These figures show how the serological improvement gradually increases from fifteen per cent. within the first six months to eighty-five per cent. within thirty-six months. The period elapsed from the date of the malaria inoculation to the time of the last spinal puncture is then very important and certainly explains the discrepancies in the percentage of the improved cases, as well as the degree of the serological improvement seen in our findings and in those reported by authors who have not taken into consideration the time factor. By a study of the cases showing serological improvement, as compared with those showing clinical improvement, it may be seen

that in the early stages there is absolutely no parallelism between the clinical and the serological improvement, but as time elapses a higher correlation can be noticed and within twenty-four months the percentage of the improved cases, both from the serological and the clinical point of view, is practically the same. Within thirty-six months the parallelism is still more striking as all of the eighteen cases improved clinically have also improved serologically. But, in addition to this, at this period of time some of the cases which showed no clinical improvement whatever now show serological improvement. The percentage of the improved cases from the clinical point of view within the first six and twelve months is 61.2 per cent. compared with 36.32 per cent. of the serologically improved cases. The percentage is highly modified in the subsequent periods as within thirty-six months the clinically improved cases represent 65.0 per cent. of the cases against 85.0 per cent. of the cases serologically improved.

There is no parallelism, in the strict sense of the word, existing between the clinical and the serological improvement, even in this later period. But while in the earlier stages the lack of parallelism was absolute, in the later period, a partial parallelism exists, in the sense that all improved cases, from the clinical point of view, show a concomitant serological improvement.

The following clinical cases are reported, in order to illustrate the course of the clinical and the serological improvement from the point of view of parallelism, as well as to illustrate discrepancies between the clinical and the serological improvement.

TABLE VI

Serological Modifications Within Twelve Months After the Malaria Treatment

Case illustrating parallelism between the clinical and serological improvement following the malaria treatment.

Case I.—F. J. F. Admitted May 24, 1920, aged thirty-eight. This patient was a lieutenant in the Navy. Fifteen years before the onset of his present illness, he was infected with syphilis and received more or less treatment for three years following the infection. During the war he was ordered to another port and he became suspicious that this was because of a plot on the part of other officers to alienate his wife's affections. He became nervous and worried and made mistakes in his work so that he was finally placed in a naval hospital, where it was discovered that he had neurological symptoms. The serological tests revealed the presence of paresis.

0000	0000	4444	0000	3 plus	00	18	2	5555554530	0011100000

The physical examination on admission revealed a well nourished and built man. Neurologically, the pupils were unequal, the right being larger than the left; they were irregular and reacted very poorly to

light, the excursion being limited. There was a marked tremor of the facial muscles, protruded tongue, and extended fingers. His tongue was deviated slightly to the right. The knee jerks were fairly active and there was slight swaying in the Romberg position. His speech was slurring and he had considerable difficulty in pronouncing the test phrases.

Mentally his stream of talk was retarded but relevant and coherent. Emotionally he showed considerable deterioration. He laughed continually while talking of his trials and troubles. He gave voice to delusions of persecution, but had no appropriate reaction to them. He was also mildly hallucinated in the auditory field. His insight was lacking and his judgment was impaired. He was oriented in all spheres. His memory for both remote and recent events was very poor. Mental calculations were poorly performed.

On April 26, 1923, this patient received the malaria treatment, with a total of fifteen paroxysms. The serological reports prior to the treatment were as follows:

June 11, 1920—Blood W.R. negative.
June 14, 1920—Cerebrospinal W.R. 4 plus, Globulin 2 plus, Cells 12. Gold Curve 55555532100.
August 4, 1920—Cerebrospinal fluid W.R. anticomplementary, Globulin negative. Gold curve 55555554432.
August 19, 1920—Blood W.R. 4 plus, Cerebrospinal fluid W.R. 2 plus, Gold curve 5555544310.
September 11, 1920—Cerebrospinal fluid 4 plus, Globulin 2 plus, Cells 23, Gold curve 5555555310.
February 16, 1921—Blood W.R. 2 plus, Cerebrospinal fluid W.R. 4 plus, Globulin negative, Gold curve 5554321000.
April 7, 1921—Cerebrospinal fluid W.R. 4 plus, Globulin negative, Gold curve 5555310000.
July 7, 1921—Cerebrospinal fluid W.R. 4 plus, Globulin 2 plus, Cells 11, Gold curve 5555553210.
September 21, 1921—Cerebrospinal W.R. 3 plus, Globulin 3 plus, Cells 17, Gold curve 5555432100.
March 22, 1922—Cerebrospinal W.R. 1 plus, Globulin negative, Cells 13, Gold curve 5555432100.
August 16, 1922—Cerebrospinal fluid 4 plus, Globulin 2 plus, Cells 12, Gold curve 5421000000.
April 4, 1923—Cerebrospinal fluid 4 plus, Globulin 2 plus, Cells 12, Gold curve 5554321000.

The serology following the malaria treatment was as follows:

November 21, 1923—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin trace, Cells 3, Gold curve 4333210000.
April 16, 1924—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin trace, Cells 3, Gold curve 3333210000.
November 13, 1924—Blood W.R. negative, Cerebrospinal W.R. 1 plus, Globulin trace, Cells 15, Gold curve—normal curve.
March 24, 1925—Blood Wassermann negative, Cerebrospinal fluid W.R. negative, Globulin 1 plus, Cells 6, Gold curve 2333221000.
September 15, 1925—Blood W.R. negative, Cerebrospinal fluid W.R. negative. Globulin negative, Cells 2, Gold curve 1122100000.
March 23, 1926—Blood W.R. negative, Cerebrospinal fluid W.R. negative, Globulin 1 plus, Cells 4, Gold curve 0000111000.

At present the patient is in extremely good physical condition. The neurological examination reveals that the right pupil is irregular and larger than the left. The pupils do not react to either artificial or natural light although there is a tendency of the right pupil to contract. The reaction to accommodation, although sluggish, is present. There are no signs of cranial nerve involvement. The ocular movements are free. There is practically no tremor of the facial muscles in the forced movements. No tremors of the extended fingers. Practically no adiadokokinesis is elicited. The fine movements of the fingers are well performed. The coordination tests are well executed. The muscular power and tonus are normal. The deep reflexes of the arm are slightly increased on the left but are normal on the right. The knee jerks are lively on both sides and equal. Ankle jerks are present and normal on both sides. No Babinski, Oppenheim or Gordon are present. The station and gait are normal. No Romberg. The mental calculations are well performed. There is no spontaneous speech defect at present nor is one detected by test phrases.

From the mental point of view, patient's stream of talk is free, relevant and coherent; he is in good touch with his surroundings; has good insight and judgment although he is inclined to be somewhat childish and emotionally slightly euphoric. No evidence of hallucinations or delusions can be obtained. He is oriented in all fields. His memory is good with the exception that he cannot recall events that transpired at the onset of his illness.

This patient was recently discharged as improved and permitted to return to his home. In his present condition he will undoubtedly be able to earn his livelihood.

Case illustrating parallelism between the clinical and serological improvement following malarial inoculation.

Case II.—T. J. T. Admitted to this institution September, 1920, at the age of forty. The family history was negative for psychopathic determinants. On June 1, 1920, this patient suffered a loss of memory and became very irritable and nervous. It appears that for two years previous to this he had had slight convulsions and speech difficulty and was quite euphoric; at times he would also become confused. On admission here he was quiet and orderly. He gave a history of having contracted gonorrhea and syphilis at the age of sixteen. For the latter disease he received mercurial treatment for a period of two years and he also had one injection of 606. No history of any other acute infections. He is married and his wife had several miscarriages; there are no living children.

Physical condition on admission showed a well built and nourished man. The right pupil was slightly larger than the left; the left reacted very sluggishly to light, more so than the right. There were tremors of the eyelids and of the extended fingers. The tongue was slightly deviated to the right. His coordination was impaired. The triceps, knee jerks and the Achilles reflexes were not elicited. The muscular power was normal. The speech was somewhat hesitating in character.

Mentally his stream of talk was coherent but circumstantial. Emotionally he was euphoric and happy. Insight and judgment were impaired. No hallucinations or delusions were elicited. His memory for both past and recent events was fair. The mental calculations were well performed.

In December, 1922, this patient was given the malaria treatment. He had a total of twenty paroxysms. Serological findings prior to the treatment were as follows:

September 20, 1920—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin 1 plus, Cells 8, Gold curve 5555554530.

February 2, 1921—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus. Globulin 2 plus, Cells 6, Gold curve 5555310000.

September 28, 1921—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin 1 plus, Cells 12, Gold curve 5543210000.

April 18, 1922—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin negative, Cells 5, Gold curve 5433210000.

November 22, 1922—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin 1 plus, Cells 11, Gold curve 4443210000.

Following malaria treatment the serology was as follows:

June 27, 1923—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin negative, Cells 3, Gold curve 3344310000.

November 9, 1923—Blood W.R. negative, Cerebrospinal fluid W.R. 4 plus, Globulin negative, Cells 4, Gold curve 3333210000.

April 9, 1924—Blood W.R. negative, Cerebrospinal fluid W.R. 3 plus, Globulin negative, Cells 2, Gold curve 4432110000.

No spontaneous speech defect and the test phrases are well repeated.

From the mental point of view, his stream of talk remains rather excessive, but coherent and relevant; he is in good touch with his surroundings; possesses no delusions or hallucinations; memory is good; insight and judgment are good; and he is correctly oriented in all spheres. Emotionally he has become considerably less euphoric. He has had no further convulsions, and he was discharged from the hospital as improved in January, 1925. Since his discharge he has been able to care for himself, and lately he came to the hospital for examination.

Case illustrating the disassociation between the clinical and serological improvement following malarial inoculation.

Case III.—C. P. Aged sixty-seven. Admitted October 21, 1921. Occupation lawyer. Family history negative for psychopathic determinants. This patient was accustomed to the daily use of alcohol. He gave no history of an initial lesion.

Physically, on admission he was emaciated and, neurologically, the examination was almost negative except for exaggerated patellar and Achilles reflexes and a slight tremor of the extended fingers. Pupils were regular and equal and reaction to light was present. Coordination tests were well performed. No adiadokokinesis, no Babinski or Romberg.

August 21, 1924—Blood W.R. negative, Cerebrospinal fluid W. R. negative, Cerebrospinal fluid W.R. negative, Globulin negative, Cells 2, Gold curve 0111000000.

March 2, 1926—Blood W.R. negative, Cerebrospinal fluid W.R. negative, Globulin negative, Cells 2, Gold curve 0111100000.

At present the physical condition of the patient is good. The pupils are regular but slightly unequal, the right being slightly larger than the left. The pupillary reaction to light is sluggish on both sides. The reaction to accommodation is also sluggish. There is a slight tremor of the facial muscles in the forced movements. Ocular movements are free. The tongue is slightly deviated to the right. There is a marked diminution of the auditory power on both sides. There is a slight tremor of the extended fingers. Incoordination of the hands appears only after repeated movements have been performed. The finger to finger and the finger to nose tests are almost normal. The deep reflexes of the right arm are

(To be concluded)

On Stomach Diseases*

JOHN WILLIAM SHUMAN, M.D., F.A.C.P.
Los Angeles, Calif.

This article is on diseases of the alimentary tract. The gastrointestinal tract begins with the mucocutaneous junction of the lips and ends with that of the anus, including the accessory organs. Its diseases are many. Stomach diseases *per se* are few, really only ulcer and cancer. However, the stomach is the "alarm clock" of the human system and "goes off" on the slightest provocation. An offensive sight, story, or odor often causes nausea and vomiting; diseases of brain, heart, kidney, lung, liver, bowels, etc., frequently disturb the stomach through reflex sympathetic nervous action. Therefore much "medicine (drugs, operations, prayers, etc.) is made" for the stomach when it really is not diseased but is only distressed.

Itis (Latin for inflammation) of the mucous membrane of the gastrointestinal tract, may be caused by irritants, for example, trauma, heat, chemicals and foreign bodies, or by infection. The name of the disease depends upon the cause and location, from stomatitis to proctitis; or from syphilitic mucous patches of the soft palate to melanotic sarcoma of the rectum. Commonly overlooked until late stages are spasms, ulcers and malignancies.

Spasm may attack any sphincter muscle from glottis to anus. None are more severe than those of cardiac and pyloric rings. The latter, not unfrequently seen in infants, the former, in fourth and fifth decades of life.

GASTRIC ULCER

Ulcer of the stomach usually gives a fairly accurate history of hunger pain, food ease, sour eructations, heartburn (meaning hyperacidity) hypersecretion (spitting up sour fluid), and periodicity of attacks. These should lead to the diagnosis of ulcer suspect. With occult blood in the stool, suspect the ulcer to be bleeding. Boring pain through to back with rectus rigidity, suspect it to be perforating.

X ray examination of the gastrointestinal tract is absolutely necessary. The barium meal should be watched as it passes through the esophagus into the stomach. The stomach's size, shape, location and mobility should be studied for four or five hours (the usual emptying time).

Ulcer yields findings such as persistent deformities, obstruction of the pylorus, hypermotility and diverticula (if penetrating type, especially on the lesser curvature and in the pyloroduodenal region). With established cancer there is hypomotility; and if obstructing—a six hour or longer residue of the barium in the stomach. Ulcers and cancer with craters may retain particles of the barium hours after the opaque meal has passed on. Unfortunately the only one hundred per cent. proof of ulcer is recognition at autopsy. Ulcer often escapes the surgeon's recognition at operation.

All ulcers should be first treated medically, i. e., by the nonirritation form of treatment. If all symptoms disappear the régime should be maintained for two or three years before stopping treatment. Gastric ulcer is frequently found in the patient who has focal infection of teeth, tonsils, sinuses, chronic cholecystitis and appendicitis. Also pulmonary tuberculosis and syphilis.

Perforation of an ulcer demands immediate operation as a life saving procedure. Gastric hemorrhage is not an indication for immediate operation. Periogastric adhesions often are. Ulcer that is not healed by medical management should be operated for.

ILEOCOLITIS

Ileocolitis is common to all ages. The causes are many. It may be acute or chronic. Amœba histolytica, hyperthyroidism and diverticula of colon, may be mentioned as a few of the causes. The acute type usually rights itself. The chronic needs specific treatment and is difficult to manage. By specific treatment is meant the removal of the cause, for example, hyperthyroidism, amœba, or arresting the tuberculous process.

The numerous diseases of the rectum often go unrecognized, because the physician fails to do a rectal examination with the eye and finger. A proctoscopic examination is not difficult. Hemorrhoids are often a result of liver disease (portal stasis) and this type should not be surgically removed, for they will return. Many diagnoses are made of cancer of the sigmoid when only chronic inflammation of diverticula exist, and vice versa. Chronic inflammation may become malignant.

OBSTRUCTION

Intestinal obstruction may be due to foreign bodies, intestinal parasites, feces, tumors inside or outside of the bowel; it may be due to adhesions and twists, in fact anything which interferes with the onward movement of intestinal contents. The higher up the intestine is obstructed and the nearer complete it is, the quicker will be death unless relieved by operative intervention.

Position of the hollow viscera makes little difference in function providing other things are equal—this in speaking of gastric and colonic ptosis.

APPENDICITIS

Appendicitis needs but passing mention here. Once diseased the appendix should be removed. Too many diagnoses of appendicitis are made and operations for the same done, when a gastric ulcer, inflamed gallbladder or renal stone is the cause of the patient's complaint. The reason is apparent. The examiner was not thorough enough, and was too willing to operate. Follow your patients to operation and check up your clinical findings with those found at the operation. Too often the surgeon handicaps himself with too small an abdominal incision, so that he can neither show the onlooker the pathology, nor make a comprehensive intraabdominal examination.

The following illustrative case was shown by Dr. G. W. Harmon, an intern at the hospital:

*Fourth of six clinics held for seniors at the College of Medical Evangelists, Los Angeles, April 8, 1926.

Case.—The patient, male (No. 242313), aged sixty-three, was admitted March 31, 1926, complaining of upper belly pain and distress of eight weeks' duration, not relieved by meals but occasionally by soda; constipation of four months' duration; weakness for four weeks previously; had lost sixty pounds in the four months; blood in stools (tarry) once or twice; occasional vomiting and nausea.

The patient was a pale, emaciated man, with carious teeth, who looked very ill. A hard tumor was found in the epigastrium from the midline to the right midclavicular line down to the umbilicus; size three and a half by three and a half inches. It was tender and slightly rough. The patient's blood pressure was 86/65.

Laboratory findings: Hemoglobin 50 per cent.; red blood cells, 2,340,000; white blood cells, 18,800, the latter possibly due to an abscess on the buttock; icteric index, 20. Stomach: Free HCL-10, total 22; no organisms, no lactic acid, no retention and no blood. X ray findings by Dr. Carter: Possible tumor in region of pancreas.

The patient refused exploratory operation, I think wisely, for he was not only a poor surgical risk but little could be done. He has little obstructive signs and symptoms at present. His loss of weight is secondary to toxemia rather than starvation. The diagnosis was carcinoma of the liver, secondary; primary lesion not determined.

2007 Wilshire Boulevard.

Pulmonary Abscess*

An Analysis of Eighteen Cases, with a Report of One, Following Tonsillectomy, with Spontaneous Rupture and Evacuation

M. SCHWARTZ, M.D.
Philadelphia

Case I, No. 37686.—M. B., aged sixteen, a schoolboy, came to the diagnostic clinic on August 10, 1925, complaining of pain in the right hydrochondrium and lower right chest, fever and weakness. His father died as the result of an accident, his mother suffers from chronic bronchitis and asthma, and one brother had been in a sanatorium for pulmonary tuberculosis. His family history was otherwise unimportant.

The patient had measles when six years of age. Six years ago he had an operation on his kneecap following an accident. Otherwise he had always been well. Three months ago I examined him, at the Eagleville Hospital, at the behest of a social agency. At that time he was pale, underweight, and had diseased tonsils and adenoids. His lungs were entirely negative, except that there was an occasional subcrepitant râle in the left apex, which was considered of no significance. Otherwise he was entirely normal. A nose and throat examination showed hypertropied and diseased tonsils, and a septum badly deflected to the left, interfering with respiration. Accordingly, two weeks ago a tonsillectomy under local anesthesia was done.

His present illness began three days ago. While sitting quietly on his doorstep he was seized with a sudden, severe pain in the right hypochondrium, which doubled him up. This was followed by chills, fever, and sweating. The pain in the right upper abdomen continued, and also involved, very slightly, the right lower chest. It did not radiate, but was made worse by motion, deep breathing, or cough. He was mildly nauseated, but did not vomit. There was anorexia, the bowels were normal and there were no symptoms referable to the gastrointestinal tract. There was no headache, but malaise was marked. There were no symptoms referable to the genitourinary, cardiovascular, or nervous systems.

The patient was a tall, thin dark boy of sixteen, with a temperature of 102°, pulse 96, respiration 30. The pupils were equal and reacted normally; there was a slight icteric tinge to the sclera. The tongue was moist and heavily coated, the pharynx congested. The neck was negative, no pulsations, no adenopathy. The chest was long, thin, and the anteroposterior diameter narrow. There were slight depressions of both supraclavicular and infraclavicular fossæ. The right lung, particularly at the base, showed diminished expansion. Tactile fremitus was absent in the right lung, from the sixth interspace down to the costal margin. Over the same area, percussion elicited a dull note, auscultation revealed an absence of respiratory sounds, and there was no transmission of voice sounds. No râles were heard, except an occasional friction rub at the level of the sixth spinous process posterially. There were some crepitant râles at both apices, more marked over the right. The rest of the lung presented no abnormalities.

Examination of the heart: the apex was somewhat diffuse; it was felt and heard in the fifth interspace slightly outside the midclavicular line. The sounds were somewhat weak, no murmurs. Sinus arrhythmia was present. Blood pressure, systolic 115, diastolic 50. The abdomen was negative and the reflexes were normal.

Though fully cognizant of the possibility of pulmonary abscess following tonsillectomy, we felt that, in view of the family history and the apparent signs of thickened pleura, we were justified in making a tentative diagnosis of rightsided pleuritis, probably tuberculous in origin. We recommended admission to the hospital for careful study. Accordingly on August 12, 1925, the patient was admitted to the medical ward in the service of Dr. A. I. Rubenstone.

In the ward, the physical signs were found to be about the same. At this time the urine contained a trace of albumin, otherwise negative. Examination of the blood on August 13th showed hemoglobin 85

*From the medical clinics Mt. Sinai Hospital, Philadelphia. Read before the Mt. Sinai Hospital Clinical Society, October 15, 1925.

per cent.; red blood corpuscles 4,000,000, white corpuscles 19,200, differential count, polymorphonuclears 89 per cent.; small lymphocytes 10 per cent.; large lymphocytes 1 per cent. On August 21st the examination showed white corpuscles 19,300; polymorphonuclears 86 per cent.; small lymphocytes 14 per cent.; large lymphocytes 1 per cent. On August 25th the white blood corpuscles numbered 28,000, polymorphonuclears 87 per cent.; small lymphocytes 11 per cent.; large lymphocytes 1 per cent., and eosinophiles 1 per cent.

The sputum was examined a number of times. It was scant and contained some mononuclears, epithelial cell, staphylococci, and pneumococci. It was persistently negative for tubercle bacilli and spirochetes. The blood culture was negative. An x ray study done two days after admission showed thickening of the pleura at the right base. There was no evidence of effusion. There was an enlarged node in the right hilus, and some peribronchial thickening in the right base. The heart was enlarged in the transverse diameter. The paranasal sinuses were negative. The temperature was septic in type, varying from 102° to 103° F. in the evening to 99° or 100° F. in the morning.

At this juncture the suspicion of tuberculosis was abandoned, and an acute septic process, such as pulmonary abscess or interlobar empyema, was considered. It is worthy of note that most of the time the patient lay comfortably in bed, complained only mildly of pain in the right lower chest, coughed only occasionally, and expectorated very scantily.

On August 25th the breath sounds below the angle of the right scapula were slightly more distinct, but at the base breath sounds were entirely absent, there seemed to be more localization than heretofore. An x ray study on August 26th elicited the following report: "There is a marked change in the pathology of the right base. Pleurisy is still present. In addition, there is a large area of consolidation involving an area about two inches in diameter, extending from the eighth interspace downward. The upper border is sharply demarcated from the surrounding lung. Early abscess formation must be considered as a possibility, although there is no evidence of breaking down in this area as yet."

On August 28th, the following note appears in the chart: "The process in the lung shows more signs of liquefaction than pleurisy. Since last night, the patient has been bringing up quantities of greenish grey sputum, probably due to rupture of an abscess within a bronchus." A bronchoscopic opinion was then sought, but Dr. Tucker felt that in view of the pleural involvement nothing should be done, as yet. He advised waiting until the process localized itself and the pleura cleared up.

The patient continued to cough and expectorate rather profusely for the following two or three days. It was remarkable that after this the temperature subsided to normal and remained so until his discharge from the hospital. An x ray taken a few days before final discharge showed a decided improvement in the pathological process in the right base. The physical examination just before discharge still revealed evidence of thickened pleura and the breath sounds were distinct. He gained in weight and strength and was discharged improved on August 24th.

The question arises: What did take place in this boy's chest? Are we to believe he had a pleuritis with a secondary pneumonities which finally underwent resolution, or, are we to suppose this to have been a case of pulmonary abscess? The history of a tonsillectomy two weeks previously, the sharply demarcated area of consolidation, the sudden coughing, and the expectoration of mucopurulent material make the latter diagnosis more attractive.

A review of eighteen cases of pulmonary abscess diagnosed and treated at the Mt. Sinai Hospital since 1916 shows that four cases followed tonsillectomy, five followed pneumonia, one followed an operation for cholelithiasis, one followed the inspiration of a tooth, and for seven no cause could be ascertained. It is interesting to note that the number of cases seems to be increasing, there being six cases in 1924 and four during 1925, whereas in preceding years back to 1916 there were only one or two cases reported each year.

The distribution as to the lobes involved is as follows: left upper lobe, three cases; left lower lobe, two cases; right upper lobe, four cases; right middle lobe, four cases; right lower lobe, three cases. In one case there were multiple cavities, two abscesses in the left upper lobe and one in the right middle lobe, and in one case there were abscesses in both left lobes and in the right upper lobe. From this it will be seen that in thirteen cases there was involvement of the right lung, while in only seven cases was there involvement of the left lung. As to sex, twelve patients, or sixty-six and two thirds per cent., were males; six patients, or thirty-three and one third per cent., were females. The age incidence was as follows: in the first decade, two cases; in the second decade, three cases; in the third decade, three cases; in the fourth decade, four cases; in the fifth decade, four cases; in the sixth decade, one case; and in the seventh decade, one case. As to the results, nine patients were cured, or definitely improved, and five died, which makes a mortality of thirty-six per cent. This coincides very closely with the experiences of other institutions.

As to the *modus operandi* of pulmonary abscess when it follows tonsillectomy, Fisher and Cohen (1) believe abscesses following tonsillectomy are due to infective emboli carried to the lung by means of the lymphatic or vascular circulation. Paul W. Ascher (2), who has done valuable work along this line at the Mt. Sinai Hospital in New York, says: "Infective agents may enter the lung first, through the air passages, second, through the blood stream by way of the venacavæ and right heart (emboli); third, by direct extension from neighboring structures, and fourth, by traumatic introduction through the thoracic cavities." He says further that "the presence of the epithelial lining and the gross pathology indicate without doubt that the usual posttonsillectomy lung infection begins as a localized lesion in the bronchus." For the production of a localized lesion we must assume the aspiration of a piece of infected tissue or blood clot. That the septic embolic lesion may occur cannot be denied. Willy Meyer (3), Glowacki (4), Chipman (5), Prenn (6), and Moore (7), all concur in the belief that aspiration of infected material is the most likely cause of lung abscess when following operations in the nasopharynx. This is further borne out by the fact that the symptoms of abscess usually

come on about the second or third week following operation. For it is logical to suppose, if the cause was due to embolic infection, the symptoms would come on within a day or two.

Lambert and Miller (8) studied ten cases of lung abscess bacteriologically. They found anaerobic bacteria such as spirochetes, predominating in eight cases, while two cases had streptococci. Of the cases studied at the Mt. Sinai Hospital, the sputum or the pus obtained contained streptococci, pneumococci, or micrococcus catarrhalis.

It is generally agreed that the right lung is more frequently involved than the left. For as Chipman (5) says: "The right lung is involved more than the left because the right lung is larger. The bronchus is larger and straighter than the left, so that the entrance of infected material is more direct and easier than the left." In an analysis of 202 cases of pulmonary abscess following operative work on the upper respiratory passages, W. F. Moore (7) found involvement of the lower lobes of the lungs in sixty per cent. of the cases, right lobes forty-one per cent., and left lobes nineteen per cent. This is also in accord with our findings.

Once an abscess has become established, it may terminate in three ways: first, it frequently ruptures into a bronchus and thereby drains; second, it may become chronic; third, it may rupture into the pleura and cause empyema. An interesting case in our series which was treated by H. B. Shmookler, was that of a man, M. F., aged forty-eight, who had an abscess of the right lung which bored through the vertebræ, involved the spinal cord, and caused a very interesting array of symptoms.

It is the consensus of opinion that medical treatment usually gives the best results, and should always be instituted first. When a careful, patient medical regimen has been carried out and still fails, then surgical intervention should be sought.

Under medical treatment I include bronchoscopic aspiration, which has accomplished wonders in some of these cases. Vaccine treatment may be tried along with the bronchoscope. Of course, rest, high caloric diet, supportive medication, and postural treatment should be used.

Sex Hygiene of the New Zealand Maori

ETTIE A. ROUT
London

From time to time American medical investigators come to Europe studying various aspects of the sex problem, but none of the investigators who have called on me seem to have any adequate knowledge of the sex hygiene of the native races. What natives believe and do after they have been corrupted by modern European civilization is of no consequence: they are often bad copies of ourselves. But what they believe and do before we have destroyed their religion and broken down their customs is of immense importance to the entire civilized world, if only for the reason that natives do not suffer from the diseases of civilization—particularly syphilis.

The absence of syphilis will be denied promptly, by those who hold that Columbus's sailors first brought this disease to Europe, having contracted it themselves from American Indians. As a lay observer, and speaking without any claim to medical qualifications as a syphilologist, I do not feel that the possibility of Columbus's sailors first infecting the American Indians with attenuated forms of the spirochetes, and the Amerinds later reinfecting the sailors more virulently, has been eliminated. That, however, is not the only possible explanation.

The New Zealand Maori are said to have left Assyria some five or six thousand years ago. They journeyed first to Egypt, then across Europe to Portugal, and from there to Ancient Mexico; with the Fall of Mexico to have departed for Titicaca (Peru) via Central America (Maya); and later to have left Peru for the West, ultimately landing in New Zealand, with Easter Island as the first long halt. Thus it may be that the Amerinds themselves carried attenuated forms of the spirochete, and lit up the more virulent infection in the European sailors. But this is quite different from saying that the spirochete is America's gift to the whole world.

The truth regarding the origin and spread of syphilis still needs to be garnered and sifted. We do not yet know all there is to be known. But we do know already that yaws exists among many of the dark-white peoples (the brown race) all over the world, and it is the Stone Age dark-whites who were the earliest world migrants.

The New Zealand Maori belong to this race, and among them the most elaborate precautions were taken to prevent the spread of what they called skin disease, and it is notable that their name for Europeans is *pakeha-pa* meaning people (or village or nation), and *keha* meaning diseased, insanitary, scrofulous, syphilitic, etc.: a reference to the spreading of these diseases under European civilization and demoralization. Under Ancient Maori culture such diseases could not spread. The native dances largely prevented this. These dances were really health parades, done in the nude. It was the custom for visitors to deposit all their clothing on the threshold, and join in a dance of welcome from the village folk—who were also naked. If any member of either party were sick or diseased this would be apparent immediately. The visitors would refuse to come in contact with such folk, as a duty they owed to themselves and to the community; and the village folk would refuse to entertain neighbors whose health was obviously unsound. This mutual exclusion was seldom put into effect; the knowledge that it would

be was usually sufficient to keep persons not well from mingling with those in good health.

When visitors came from a distance, and were found to be sick, they were taken into the village, but quarantined in special buildings, which were afterwards fumigated or burnt down, and the visitors' clothing was destroyed and fresh supplies were given them as a free gift. Needless to say, any men or women showing signs of disease were not allowed to have sexual intercourse. No Maori woman would permit a man sexual access unless she knew he was sound in health, and no Maori man would endanger his health with a sick woman. Community life and the absence of clothing (excepting loin cloths as a sign of wedlock) made the necessity of such precautions widely known and enabled these precautions to be readily applied.

When the Maori reached the age of betrothal and marriage, these were public ceremonies, the important nature of which was understood from the teaching given from childhood in the Winter Schools. There the native doctors and noblewomen instructed the boys and girls in the principles of health and race culture, and the system of bodily cultivation (the native dance) was a continuous form of physical education begun in early childhood and continued whilst there was life—at any rate, movement.

Betrothal took place usually at about the age of fifteen, and it was a trial marriage, which usually lasted about eight or ten years. During that time the young couple lived together in the homes of either family, nominally as brother and sister, but actually as lovers. They were not allowed to have intercourse till both parties had been medically examined, and found in perfect health, and the first sexual union was a public ceremony—a sacred act calling for the highest love and reverence. Instructions were given to the youth privately, and demonstrations of posture were explained to them. The maiden could attend these, or she was permitted to obtain the information from her lover.

The eight or ten years of betrothal were infertile, and if the couple were satisfied with one another, they were later publicly married, provided they were passed as fit for parenthood. Only the highest and fittest men were permitted to become fathers: no Maori woman would allow herself to be impregnated by a second rate man. She might be in love with such a man, and live with him as his wife, but she selected only the highest type of man as the father of her child. Her husband would still consider himself fortunate because she continued to love him, and he honored his wife for fulfilling her sacred duty of race improvement. The children were regarded as the treasures of the community. It was seldom that a man had more than one wife, but if he did both wives were regarded as the mothers of all the children, even though one might have had no children.

In Maori life there was no such thing as prostitution or loveless relationship. Adultery was regarded as loveless intercourse, inside or outside marriage, and highly reprobated as injurious to race culture. Few women were denied the privilege of motherhood granted by the community, but only the best men were accorded the honor of parenthood. In the matter of race improvement, the Maori scientists taught that the father was of much more importance than the mother.

Mutual sexual happiness and mutual satisfaction were taught as essential to married life. The young man was told that it was his duty to make sure that his wife had her orgasm. If he ejaculated before this occurred, he was taught that he should allow the woman to assume the superior position till she reached her climax. Not mutilation of the genitalia but cultivation of the pelvic musculature was the way to ensure marital efficiency and mutual satisfaction. The native dances gave the necessary bodily cultivation (I have detailed these women's exericses in my book, *Sex and Exercise*—Heinemann),[1] and the teaching in the Sacred Legends gave the necessary knowledge. But before marriage and parenthood, sex experience was a sacred duty for all Maori men and women. The betrothal gave the opportunity for this, but if the couple were unsuited it was their duty to select other partners more helpful in securing personal happiness and race improvement.

In regard to the control of fertility, some of the native teaching I have set out in *Safe Marriage* (Heinemann) and some in *The Morality of Birth Control* (John Lane), and a little more has been noted in *Maori Symbolism*;[2] but the whole problem requires detailed investigation. South America, perhaps Mexico, and parts of Polynesia are still the best places in which to study the native sex hygiene of the westward stream of dark-white migrants. Among these, I believe, it will be found that circumcision was practised only when necessary temporarily to curb youthful sexuality. The hymen was removed at birth usually—certainly before the love-betrothal. Certain leaves, herbs, roots and nuts were believed to induce temporary sterility if thoroughly chewed by the men and the women at stated intervals. Possibly this is one reason why there is so much chewing of the betel nut (Arica) in various parts of the world. The leaves of the shore convolvulus are also used. Whether these produce temporary sterility or early miscarriage, we do not yet know. Abortion was condemned by the ancient Maori and preventive methods advocated. These preventive methods possibly included certain body-dances done by women not desiring pregnancy. The rectum and vagina were habitually washed out by suction and expulsion of water, sometimes from calabashes shaped like our rubber "sprays." Tampons of moss and seaweed and other substances were sometimes employed. When malposition of the uterus was produced (to prevent further reproduction) this operation was performed at childbirth, but it was done only when permanent sterility was desired. Birth control precautions and all matters connected with marital efficiency, maternity, and sex-life generally were discussed at the mothers' meetings held during the periodical seasonal ceremonies.

These are some of the ethical and hygienic principles which we may learn from natives, once we assume the right attitude of mind towards our fellowmen.

The Principles in the Treatment of Cancer*

RICHARD J. BEHAN, M.D.
Pittsburgh, Pa.

(*Concluded from page* 547)

In a somewhat similar way, Neuberg and others used agents such as cobalt, silver, copper, platinum, gold, tin. They thought that these substances produced a contraction of the bloodvessels and that (since there are no bloodvessels in the tumor) the tissue spaces in the tumor would become dilated because of the increased vascular pressure and proportionately more of the injected substances would enter and remain in the tumor than in other areas of the body. The injected substances would then act directly upon the unstable tumor cells and destroy them before the circulation was again restored to normal. No tumor has so far been cured in animals by this means, probably due to the fact that tumors in animals are sursounded by protective walls, usually of leucocytes or lymphocytes, and it is difficult for the injected materials to penetrate into the tumor itself. This protective wall does not exist to such a degree in man, where the tumor progresses more by infiltration. Opitz has been studying very systematically the effects of drugs upon cancer. Among the substances he has tested are iodine preparations. After considerable study, he evolved a combination which he calls No. 67. This contains glandular extracts, dyes, chemicals, etc., the exact composition of which at present is not published.

VACCINES AND EXTRACTS

It has been found that animals usually do not have multiple carcinoma. It has also been found that in mice in which a spontaneous tumor of the breast is present, irritation cancer can, with difficulty and in but very few instances, be produced. It is claimed by some that it cannot be produced at all. The presence of a primary cancer in man apparently acts as a hindrance to the development of another primary cancer, because it is extremely rare to find cancer of the same type in two different locations in the human body unless one follows the other and is of metastatic origin. This restriction does not, however, apply to the skin for multiple epitheliomata apparently are frequently present. Therefore, cancer apparently causes a protective substance to be formed in the organism. This immunizing or protective substance persists even when the primary tumor is removed. It is of variable duration. It seems that it is the breaking down of this immunity that permits the underlying causative tendency to reassert itself so that new formations of cancer tissue again occur. The socalled recurrence in the primary carcinoma area as the breast or in the operative incisional scars following cancer operative removal, may be due, not to oversight of the surgeon in leaving cancer cells in the tissue, but to the reestablishment in the organism of a lessened resistance to localized tissue overgrowth.

Llambias and Gretto-Brian found that inoculation of an animal that had been previously injected with a filtrate of chicken sarcoma will, on implantation of the chicken sarcoma, give only an attenuated growth. If another animal is injected with the same tumor filtrate and then is innoculated with the attenuated growth of the first animal, it may or may not produce a growth in the second animal. However, if a third animal which has been treated with the injection of the same tumor filtrate is inoculated with the attenuated growth of the second animal, there is always a negative result, showing that by injection of the tumor filtrate a direct action upon the transmissible principle which causes the development of the tumor is produced. As chicken sarcoma is practically one hundred per cent. inoculable, the above experiments indicate that there has been developed a positive deterrent action against the activity of the tumor cells.

Further, Woglom, in discussing tumors which spontaneously retrogress, says, "the cells of a tumor that is to recede are destroyed first at the periphery by a lethal agent or condition which gradually permeates the neoplasm and that the dead cells in its wake are soon replaced by a secondary fibrosis." He further states that "no clue respecting its nature has as yet been discovered; certainly there exists no evidence that it resembles any of the known antibodies." Because of the fact that the retrogressive change first occurs beneath the capsule and even adjacent to capillary vessels, it would indicate that the immunizing principle is in some way connected with the connective tissue and is not free in the blood stream.

It has been thought that active immunity may be produced against human cancer after its removal by the implantation of cancer tissue which has been rendered inoculable by lethal doses of x ray. This I have discussed earlier in my paper.

It has also been found that innoculation of mice with various normal tissue cells produces variable immunity. Living cells injected into the circulation of an animal were slowly eliminated; but on second injection into the same animal, they were rapidly eliminated. The first injection sensitized the animal and on the second injection destruction of the cells occurred. It is also of particular moment that cells which act as sensitizers need not be of the same type as that of the tumor against which they are directed.

Applying these facts, Keyser injects dead cancer cells made into an emulsion which he calls a vaccine after cancer has been removed by operation or other means. These cells are foreign proteids and may in some way stir up a sensitization of the animal against the cells of a tumor which, the conditions being favorable, would otherwise develop. He finds these vaccines are of some value in conjunction with other methods of treatment. For the purpose of producing protoplasmic immunity, he makes extracts of cancer cells and injects them into the organism. These are active remedial measures against cancer tissue itself. It is possible that they may act as sen-

*Read before the Buffalo Academy of Medicine, November, 1925.

sitizers, rather as activators, so that the normal cells of the body may be stimulated to the production of an antibody?

We have been experimenting with both vaccine and extracts at the Pittsburgh Skin and Cancer Foundation. So far, the vaccines have been useless, but we believe that possibly some success has attended the use of extracts. I use the term "possibly" because it is very difficult to evaluate the effect of treatment since there is no definite rate of growth of tumor tissue and no standard comparison upon which to formulate an opinion.

From time to time organisms supposed to cause cancer have been defined and isolated: I refer to the bacilli of Glover, of Young, of Blumenthal, of Nuzum and of Gye. That such bacilli occur is a source of controversy; these I have discussed earlier in my paper. Antisera have been produced and their sponsors claim some curative results from their use. Up to the present, none seems to have any definite curative influence. Vollmer found that protein injection caused a change in metabolism, an initial acid phase giving rise to an alkaline phase; small amounts seem to stimulate; large amounts to paralyze. It is also possible, as stated by Weichardt (14), that "the broken down products of the proteins are immediately taken up by the cellular elements of the body and that the latter immediately react with increasing efficiency of all functions."

T. Lumdsen (15) produced an antiserum which when injected repeatedly into and around a sarcoma on a rat's leg with temporary restriction of the blood supply, caused the tumor to disappear. The rat was now immune and subsequent inoculations of the same type of tumor did not take. If there were two tumors, one on each foot and the one was removed by constriction of the blood supply and the injection of antiserum, the tumor on the other foot disappeared. Lumsden thinks that the products absorbed from the attenuated or dying cells evoked an active immunity in the host. Note the associated constriction of the circulation which corresponds to the conditions present when we restrict the circulation by arterial ligation.

Where there is a marked anemia with a leucopenia, it is advisable before beginning treatment to get the patient into as good physical condition as is possible. For this purpose blood transfusion is frequently indicated. Should the case be far advanced, palliative means are then instituted. Morphine and other pain relieving drugs are to be given. X ray in some instances may relieve the pain.

Coincident diseases: 1. Tuberculosis was found in twenty-two cases of 180 consecutive autopsies on cancer patients; it nearly always was found in the primary lesion. White thinks that in most cases the tuberculosis was secondary to the cancer (White).

2. Syphilis: When syphilis occurs in association with cancer, as it frequently does in cancer of the tongue, it is held to be very dangerous to force the arsenicals and mercury.

Measures should be undertaken by surgical or other means to correct the sequelæ, such as deformity or increased sensibility or loss of motor function, the sensory and motor changes which are due either to lessened circulation or to pressure upon the nerves, resulting from injury either at the time of operation or as a consequence of the contraction of postoperative scar tissue.

When because of extensive involvement, it is necessary to destroy the nerve supply to a muscle, function may be reinduced in the muscle as in the orbicularis oris, by suturing into the affected muscle a pedunculated graft of the temporal or the masseter muscle; this is the method of Gersuny, proposed in 1906, proved experimentally by Erlacher in 1914.

The best means available to relieve the painful reactions, especially in the hand as occurs after complete dissection of the axilla and infraclavicular areas, is diathermia. It is of great value. Injection of alcohol into the Gasserian ganglion or one of its branches is used to relieve the pain in tumors of the face or mouth. Injection of the cervical roots has also been done in cancer of the neck.

Deformities should be treated by the proper corrective measures.

I wish to call your attention to certain facts that we should always remember, especially if our enthusiasm or the urging of a clamoring patient should tend to lead us astray, namely, that the cure, i. e., the retrogressive process of a cancer cannot be forced; and, if the attempt to do so is made, a stormy and possibly dangerous reaction may occur, with, in some cases, fatal results. Opitz states that in two instances in man and frequently in animals he has observed death intervene during the rapid retrogression of a carcinoma.

It is also necessary that periods of freedom from treatment be given irrespective of the type of treatment, in order that the organism may develop either a resistance to the poisonous products of disintegration of the tumor, or a means of destroying or extruding them.

I would also add a word of warning to the indiscriminate, uncontrolled use of radium and of x ray. I believe in many cases, irremediable harm has been done by the ill advised and pernicious interference by those of insufficient experience. The cancer patient is in a class all by himself and demands the best assistance that is available. We should not limit ourselves to any one means of treatment, nor should we direct our efforts only to the growth and its destruction but that we should devote more attention to the host—for after all, it depends upon the general reactions of the patient whether recovery or death results.

Practical Therapeutics

Intravenous Therapy*

JOHN HOWARD FRICK, M.D.

Philadelphia, Pa.

Since Lugol's solution was first introduced in the treatment of diseases of the thyroid gland discussion has been both pro and con as to its efficacy. In some clinics where iodides were employed it was found to be of use only in the simple hypertrophic and exophthalmic varieties. Some clinicians employ the tincture of iodine in doses up to a dram t.i.d. in toxic adenomas with beneficent results. In other clinics it was found that the employment of iodides in any form resulted in an apparent onset of crisis with all of its terrifying phenomena. It was this unusual result and peculiar iodide action that first called our attention to what we believe is a method of determining the difference between ordinary exophthalmic and the toxic goitre. If our surmise is true we may have in our possession a method by which we can definitely tell, just as in the Goetch test, when a goitre is becoming toxic and endangering the patient's vital organs. This will be of great help clinically in order definitely to determine the treatment best suited in each particular case. In order to make the test accurate it is necessary for us to employ the particular concentration of sodium iodide that has been determined, both experimentally and clinically, as being the proper concentration for use in the blood stream, namely, one gram for every 45.3 kilos body weight, said one gram held in 10 c.c. sterile water. Suppose we have a case of enlarged thyroid of some years' standing and we wish to determine the toxic factor. With the proper intravenous injections of sodium iodide with hourly records of pulse and blood pressure this is accomplished. If in the toxic stage or approaching a crisis there will be an increase in pulse rate, a primary rise and a secondary fall in blood pressure which will not return to normal until after the expiration of the twenty-four hour period. It is apparently possible by this method to determine and establish the point at which the exophthalmic goitre goes over into a toxic type. In two cases we have been able to influence the metabolic rate by this method of treatment, both having a reduction of from forty to fifty per cent. in the metabolic rate after the intravenous employment of sodium iodide. The report of Jackson (5) states that the use of iodine prevents or terminates the fatal crisis in exophthalmic goitre and further states that the nervous, renal and digestive systems are favorably influenced and there is an average reduction of plus nineteen per cent. in the basal metabolic rate.

Up to the present there has been no method by which one could determine when an exophthalmic goitre became toxic. With the employment of this method where we get direct reaction to the iodide molecule we are reasonably safe in assuming that the element of toxicity exists and can be guided accordingly. In a few cases where there was a profound reaction to the intravenous injection of the sodium iodide marked by the increase in the pulse rate and a decided fall in blood pressure, on again repeating the treatment after the third or fourth day this did not occur to the same degree and after the third or fourth injection there was no longer any reaction and the metabolic rate very much lowered. Thus we are led to feel that sodium iodide employed in this manner constitutes not only a test of the toxicity of a patient but provides a method of detoxifying. This is referred to by Jackson in his work on goitre.

Sodium iodide is apparently of value in the controlling of hypertension. In a series of fourteen cases of high blood pressure that have been studied over a period of two years the administration of one half the normal amount of sodium iodide at weekly intervals has brought about a reduction in blood pressure of about twenty per cent., this without any other form of medication, the essential being regularity of treatment over a long period of time, usually about six months.

Some few of these cases have had the usual complications, cardiac, renal, hepatic, all of which seem to be benefited by treatment. In a similar series of ten cases of hypertension in which sodium iodide and potassium iodide were given orally no such results were attainable at the end of a similar period and besides the patients invariably complained of gastric discomfort incident to the iodide effect.

Calcium chloride has been repeatedly employed in the control and treatment of pulmonary hemorrhage, to lower the coagulation time of the blood, to control or prevent postoperative tetany in thyroidectomy, in the control of night sweats of tuberculosis, and in the control and treatment of tuberculous enteritis. It is important that we realize that calcium chloride is inefficient and inactive when given orally, this having been definitely proved by Hastings and MacIntosh (1). These investigators have shown conclusively that the oral administration if continued will produce a severe acidosis whereas the intravenous administration, even over a long period of time, shows no untoward effect. Repeated examinations of the blood after the injection of the calcium show its entire absence after six hours while there is no increase in the daily excretion of the calcium in either urine or feces for six days after the injection, thus proving conclusively that the calcium is put to some use or enters into some combination in the body.

The dose that has been found most appropriate, namely ten c. c. of five per cent. solution, is under ordinary conditions devoid of any reaction and is practically safe to employ in this concentration. The patient complains of a burning sensation usually in the tongue and then over the entire body. In two cases of tetany in which calcium chloride was given orally along with parathyroid extract, as has often

*Read before the American Therapeutic Society on June 10, 1926, at Philadelphia, Pa.

been advocated, there was a control of the contractures or recurrence of the tetany. After ten days of treatment by the oral method it was decided to give the calcium chloride intravenously with almost immediate cessation of the symptoms and after six or eight daily injections there was no return of the condition.

The Treatment of Hepatic Venous Cirrhosis

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

The curable types of the pathological process under consideration are above all the hypotrophic forms, in which the compensating hypertrophy decreases the syndrome of hepatic insufficiency and portal hypertension. In atrophic cirrhosis—still designated as Laennec's type—we cannot at present affirm that curable forms of hepatic sclerosis exist, but it can be asserted that the cirrhotic process can be controlled if hepatic insufficiency be detected at its very onset.

The clinical evidences of hepatic insufficiency are the first to appear in venous cirrhosis, hence great advantage is to be derived from their early detection. The symptomatology of minor hepatic insufficiency comprises numerous little signs, often not apparent, such as trifling digestive disturbances, apt to be regarded as common dyspepsia or else accounted for by an alcoholic gastritis, because patients subject to this morbid process are very often—although not invariably—large users of alcohol in its various forms. The patient's general health is reacted upon, the symptoms being an unaccustomed apathy, somnolence and fatigue. There is an early tendency to hemorrhage—epistaxis especially—and the development of hemorroids and purpuric elements in the skin.

Minor hepatic insufficiency is quite compatible with a fairly good state of health and not infrequently is detected by the urinary syndrome. Oliguria and analysis of the urine will show the presence of hypoazoturia, indican, urobilin and occasionally bile pigment and salts, due to dysfunctioning of the hepatic cell. Although far from reliable, resort to the test of alimentary glucosuria, experimental ammonuria, the coefficient of acidosis and nitrogen is advisable and may give results.

One of the best means of dealing with hepatic insufficiency is hepatic opotherapy, as it stimulates the biliary functions, increases the ureopoietic function, increases the anticoagulating and antitoxic functions of the liver, likewise its glycogenic function, and induces diuresis. Injectable gland extracts are approved by many given either subcutaneously or in the muscles. In urgent cases the intravenous route may be selected. The aqueous extracts are preferable, but the preparation must be freshly made and discarded after two weeks time.

Vallaret is of the opinion that lipoid extracts have an injurious action on the hepatic parenchyma and I am of the same opinion.

The exhibition of gland extracts by mouth is, we have found, quite reliable in so far as the therapeutic action is concerned, but only when the digestive functions are not involved, otherwise their absorption will not take place. The two methods may be combined, an injection being given on one day, and powdered liver, the various extracts in cachets or pills on the following day, and so on. Fresh finely hashed pig's liver—from 100 to 200 grams, macerated in vegetable soup and the filtrate drunk—is not to be despised. Hepatic opotherapy may be combined with pluriglandular treatment which enhances the effect of the former, in the form of extracts of bile, pancreatic and intestinal juices. Even when long continued hepatic opotherapy rarely gives rise to intolerance other than diarrhea which is not common.

The action of the gland extracts may be reinforced by the exhibition of boldo in the form of fluid extract or tincture or infusion of the leaves on account of its powerful tonic and diuretic properties, as well as its cholagogue action.

When the venous circulatory disturbances depend largely upon hepatic insufficiency, the subject usually will at the same time present clinical manifestations dependent upon portal hypertension. The early appearance of urinary disturbances—opsiuria, anisuria and oliguria—decrease of the urinary output from orthostatism and massive absorption of water; of circulatory disturbances in the shape of collateral circulation of portal or cavoportal type, hemorrhoids, possible gastrointestinal hemorrhage and splenomegalia; and lastly, the occurrence of ascites. All these morbid phenomena are proofs of portal hypertension that can be detected early in the process.

For disturbances of diuresis it is necessary first of all to limit the amount of fluid ingested. It must not be forgotten that these disturbances are not due to renal insufficiency and that they are above all evidences of cavoportal circulatory difficulties due to a real barrage offered by the liver. The hepatic gland opposes resistance to the return circulation, while above it sets up an intense venous congestion throughout the gastrointestinal tract resulting in a hindrance to absorption of liquids, while at the same time it sets up venous congestion of the kidneys in turn producing venous hypertension in the renoportal anastamoses. Hence is explained the fact that beyond the liver there is restriction of the blood supply, the arterial hypotension being the most faithful index of this state of affairs.

Therefore, it is a matter of mere common sense to limit the amount of liquid ingested. A milk diet, which is the treatment of choice in all cases of hepatic

insufficiency, should be resorted to with moderation and better in the solid form, namely, fresh cheese, curdled milk, kephir or yaourt. All things considered, not more than 200 c. c. to 300 c. c. above the twenty-four hour urine output are to be allowed. For obvious reasons, it is useless to have recourse to the usual diuretics in hepatic cirrhoses. If, on the other hand, it is desirable to eliminate the retained fluids which are neither absorbed nor excreted by the organism, the use of purgative medication finds its indication. It is all the more effective because it causes the elimination of a large quantity of accumulated fluid to be excreted by the intestine, hence reducing the tension in the portal veins. The best drastic purgatives today are the same as were used two hundred years ago, namely:

Ext. colocynth. comp. (U. S. P.). 50 centigram. F. s. a. pil. moll. no. I.

D. S. Take in the morning on arising.

A less energetic method—old as the hills but efficacious—is to order a soupspoonful to be taken every hour of the following:

Rad. althæ 10 grams.
Aq. dest. q. s.
for decoction of 180 cc.
Add:
Potassii bitart. 15 gram.
Syr. rub. id. q. s. ad 250. c.c.

This medication, useful in the disturbances of diuresis, is also one of the best at our disposal for portal hypertension.

It is clear that a severe diet is essential in cases under consideration, which must take into consideration the two essential elements, viz., hepatic insufficiency and portal hypertension. To overcome overwork of the insufficient hepatic parenchyma and render absorption easier in the congested digestive tract, the meals should be small in amount and frequently partaken of. Six meals a day, at 8 a. m., 10 a. m., noon, 4 p. m., 8 p. m., and 10 p. m. will be found satisfactory. At each, the patient should eat a small amount, the diet being largely lactovegetarian. Vegetable broth, milk in the form of soup and whey and boiled meats. The food should be poor in carbohydrates, albumen and especially fats, the hepatic lesions causing the parenchyma to be intolerant of them. Cooking must be done with cream and fresh butter. White sauces, thin soups, macaroni, cooked peeled vegetables, excepting cabbage, tomatoes, truffles, mushrooms and sorrel, carrots, cooked fruit, sweets containing little sugar and eggs, non-acid preserves and jellies and dry cakes, raw peaches, grapes (without skin) and bananas may be indulged in prudently.

The cirrhotic subject should consume little bread and then only the crust. He should avoid all sea food, eggs, pork, highly seasoned cheese and sauces, pepper, mustard, vinegar and lemons, oil and fats, coffee and chocolate. It goes without saying that alcohol in *any form* is to be strictly prohibited. After a time, when the patient may be allowed a little meat it should be roasted or broiled without butter, white meat being preferable. The patient should drink between meals, not during them. He should lie down after each meal for about thirty minutes. Complete rest in the clinostatic position—especially after meals—is necessary to favor diuresis. Orthostatism decreases the urinary output.

Between meals the patient should drink a hot infusion of boldo or orange leaves in small amount and while in the recumbent position. Tobacco in moderation may in most cases be allowed.

Finally, massage and dry friction of the body, methodically carried out, help to stimulate the hepatic cells and in this respect the hot douch under water as practised at Vichy is beneficial.

I now come to the treatment of ascites. The abdominal swelling preceding the production of the intraabdominal fluid collection is such that it often conceals small collections, but these may be detected by rectal or vaginal digital exploration. However, their pelvic evolution is of short duration, not more than a few months. If the swelling is very considerable, it is better to insert a permanent rectal catheter than to resort to premature and useless paracentesis, because the fluid soon collects again after it has been withdrawn. When the patient is too frequently tapped, serous anemia ensues and not infrequently secondary infection arises.

The proper time to resort to paracentesis is when the collection has reached about several litres, the abdominal walls being sufficiently tense and the umbilicus unfolded. Tapping should be done at once if the abdomen becomes painful, if the respiration is interfered with or if marked edema of the limbs occurs. The immediate necessity of paracentesis is clear when there is thoracic oppression with a sensation of distress, palpitations and persistent insomnia. There are no real contraindications for tapping, regardless of the patient's general condition. If the patient is seized by cardiac collapse, if there are evidences of serious hepatic insufficiency or if the subject is adynamic, one may rightly hesitate. Pregnancy is not a contraindication, but the operation must be prudently carried out.

It is all important to withdraw the fluid slowly until the flaccidity of the abdominal walls and pink color—sometimes cramp—indicate that evacuation is well advanced. The abdominal cavity must not be emptied to the extent of dryness, because gastro-intestinal hemorrhage may ensue, the result of the law of equilibrium of localized portal hypertension (Villaret), and occasionally hemorrhages from the mucosæ or purpura. After occlusion of the puncture wound, a thick layer of cotton batting is placed over the abdomen and a well applied broad bandage exerting an even pressure completes the dressing.

After paracentesis the edema of the limbs retrogresses and absorption of larvate edemas occurs. Edemas occurring in venous cirrhosis have a special mechanism and although a moot question, it would seem that they depend upon the hepatic parenchyma and are wholly different from those due to chloride retention. For this reason a saltless diet is never satisfactory and as far back as 1906, Villaret showed that the edema in these cases did not increase when large amounts of salt were ingested. Of late some observers have even advised hyperchloride diet because of the diuretic action of sea salt. Autoserotherapy with the ascitic fluid advised by Gilbert, of Geneva, has failed to prevent ascites and may prove dangerous, unless the circulatory system and kidneys are in perfect functional condition which is not the case in venous cirrhoses.

Clinical Physiotherapy of the Liver*

JOSEPH RIVIERE, M.D., P., Sc.D.
Paris

"Of a hundred diseases, says Boerhaave, there is hardly one where the liver will not be affected." The liver is the great chemist of the organism (Richet): it is for that reason that it intervenes in all deviations of metabolism. The bile possesses the important digestive mission of emulsifying fats. It sweeps and cleanses chylifers, after the laborious work of absorption, and it exercises on the intestinal mucus an anticoagulative power. As an antiseptic, it tempers the visceral putrid fermentation.

The vascular liver, besides its glycogenetic function, elucidated by Cl. Bernard, possesses also the hematopoietic mission of elaborating blood, the "martial function" of Dastre, insuring the formation of new corpuscles, by a special power of cytopoiese.

Finally, clinical medicine has led me to see in the liver the great purifying manufactory of the system. I have called it "the defecatory liver."

In my communication on the abortive and curative treatment of acute diseases by calomel, castor oil, heat and water, I showed that the bile is composed of the bulk of the excreta of the organism and that its regular elimination by way of the intestines is necessary to the vital equilibrium and to the cure of diseases. The hepatic gland is the purifying organ in an eminent degree, the seat of biochemical activity, the laboratory of life and health.

The prosperity of many diatheses and particularly of arthritism, humoral acidism, is intimately united with the deficiency of the liver. The intoxication which is derived from it (poisons of autolysis), also the bad elaboration of protein substances, create renal insufficiency nephritis, chloride retention with oliguria.

A real vital manometer, seat of chemical changes, reserve of heat and nutriments, defensive and antitoxic barrier, manufactory of urea, uric acid and purines, hypotensive gland of which hyperemia is sometimes providential, the liver protects us also from infectious diseases and particularly from tuberculosis. Its complete integrity is indispensable to our individual prophylaxis. A sound liver utilizes and exalts all our energy. It is absolutely necessary for good health.

*Read at a meeting of the New York Electrotherapeutic Society at the New York Academy of Medicine, October 6, 1926.

The liver readily reacts on the stomach and manifests its defective state by digestive atony, nausea in the morning with dizziness, hyperchlorhydric gastralgia and other conditions. So the sufferer from lithiasis nearly always localizes in the stomach his painful paroxysm. However, that does not prevent the lithiasis from often producing a state of hyperpeptical dyspepsia, which may even attain hematemesis.

All the factors of physiotherapy have a beneficent action on the liver, but chiefly those which possess more general effect on the nervous and on the vascular system: X rays, actinotherapy, thermotherapy and d'arsonvalization. Diathermic penetration has seemed to me, for several years, to be the chief cornerstone of the treatment in most hepatobiliary deficiencies. It resuscitates the cholagogue function and improves the proteolysis, restores all the deficiencies, calms the irritability of the gallbladder and congestive disorders, stimulates the cellular diastases of the liver, facilitates the formation of the urea, raises the azoturic relation and restores the compromised digestive assimilation. All these effects are due, certainly, to an action on the vagosympathetic system.

Soon we will show the excellence of diathermy as a treatment of cholecystitis and angiocholitis, the soothing of gallbladder pains and cephalic attacks which accompany them, the raising of the general hypothermia, etc. Our American colleagues, who have made the masterly studies in diathermy that you all know, attributes its favorable effects to a trophic power due to the exaltation of the leucocytic defence.

Before proceeding to surgical procedures, never forget the physicotherapeutical cures, which often succeed, even in troublesome cases.

DEFECTIVE LIVER

Its symptoms are anorexia, dyspepsia for fats; insomnia and invincible somnolence after meals; constant general lassitude, more apparent in the morning than in the evening; a rather frequent sensation of discomfort and gastric fullness, with hot spells, yawning, belching, hiccough, meteorism, epigastric pains, chilliness, urticarial rashes. The disposition of the patient changes; he becomes sad, anxious,

pessimistic, with marked depression of will. The complexion becomes yellowish and the skin dry; the gums bleed and the pharynx is congested.

Heavy eaters and drinkers, sedentary, infected and toxic persons, arthritics, the obese, pregnant women, wet nurses, and those afflicted with the menopause or with acquired or hereditary syphilis are predisposed to hepatic deficiency. In pulmonary tuberculosis (especially when ethylism is associated), the hepatic function decreases and this *méiopragie* contributes singularly to the nutritive decadence, to circulatory trouble, to epiploic and hemorroidal pains. Hepatic deficiency readily creates a kind of hemorrhagic or hemophilic diathesis, expressed by purpura, epistaxis, menorrhagia and metrorrhagia. This predisposition, which Weil recently described under the name of "hemogenia," manifests itself also by a strange fragility of the capillaries, a tendency to varicosities, to facial congestion, blotchiness, more rarely to basedowism or latent myxedema.

On the other hand, hepatic deficiency hinders the uricolytic function of the liver, and favors a state of hyperuricemia, fertile in various accidents, formerly confused with gout and rheumatism; many articular and muscular manifestations, topalgia, neuritis, and other atypical nervous accidents, arterial cardiopathies, melanodermias, and other conditions depend on the torpid liver, the most important tributary of arthritism.

The properly called biliary deficiency, or dyscholia is an important cause of mucomembranous enteritis. The absence of bile in the intestine is indeed fatal: for this secretion possesses on its mucous membrane, an effect so to speak tutelary, antiacid, emulsive, anticoagulative of the mucus, antiseptic, antiphlogistic and peristaltic to the first degree, by its special stimulins, which awaken the falling activity of the smooth fibres.

The treatment of the hepatobiliary deficiencies, dyshepaties and dyscholies, consists in favoring the cellular functions by the cholagogues (calomel, salicylates, podophyllin) which by removing cholesterinemia, cause that viscous polycholia to disappear, premonitory of icterohepatic attacks and also often a prelude to arteriosclerosis.

Copious beverages (coffee and tea) will assure a beneficent diuresis and alleviate the abdominal venous plethora by their dialytic action.

In case of chronic deficiency of the liver, the therapeutic agent required is the complexus of all the agents, which offer by their association the maximum of curative potential, capable of reviving in an almost certain manner, the hepatobiliary ferments. The physical agents have the immense advantage of multiplying the therapeutic power of the medicinal agents and of facilitating their toleration; an important result, in a dysfunction, which breaks down every antitoxic barrier. It is indeed by gradual toxemia that the decrease of vitality is latently produced. The physical agents, more biliary than cholagogic, in general are able to resist cellular inertia, and also paresis of the gallbladder and the hepatic duct; it is especially by this therapeutic process that they restore to the liver its biological activity, also sustained by the use of calomel, purgations, cholagogues, salicylate and bicarbonate of soda.

On the other hand, physiotherapy is notably valuable for protecting the fragility of the hepatic cel against infections and intoxications.

We have frequently noted in treating these complex, pathological and illdefined conditions, resulting primordially from the reaction of the intestine on the hepatic apparatus: the "colonial liver," histological alteration of the organ by poisons invading the bile duct and the portal system. The physical agents then regenerate the vesicular cells and change the diseased mucous membrane of the bile ducts, while removing for the better, the abdominal venous plethora.

CHOLELITHIASIS

Three times more frequent in women than in men cholelithiasis appears readily at the menstruating periods or during puerperality. I have seen it show itself, sometimes, in the form of cardiospasm, accompanied by sialorrhea, noisy eructations and aerophagy. The visceral cramps follow afterwards and the classic hepatic colic comes on after those initial manifestations.

The genesis of lithiasis is explained by biliary stagnation, causing a desquamative angiocholitis, which is complicated by ascending microbism, usually coming from the duodenum. It is also supposed that vesiculocanaliculary scratches may be followed by a fibrous process, whose etiological rôle we shall soon appreciate in speaking of cirrhosis.

Obstinate and rebellious constipation usually accompanies lithiasis. It is to faradization and particularly diathermy that we must have recourse to reestablish the intestinal function in its regularity and suppress the typhlic or cholecystic complications which lead to surgery. Radiological examinations show these morbid hybridities, whose discrimination dates from only the last few years. By diathermy, conscientiously applied, we shall ordinarily evacuate the deposits of stagnant and more or less infected bile; we shall drain the congested biliary ducts, septic or simply affected with *lithogène* catarrh. The patient's complexion will become clearer and his digestion improves as *mastic* stools will regain their normal coloring, as well as the mahogany urine; sick headaches and insomnia, both of cholemic origin, will disappear, at the same time as the icterus and coprostasis. These happy results will be obtained without pain, without colics and without diarrhea.

Under the heading of "little symptoms of hepatism" various authors describe on the whole, the forerunner syndrome of biliary stones "prelithiasis." Sensitiveness of the right *hypocondre,* weighty, swollen sometimes, with shooting pains, if one feels the vesicular region (the x rays localizes perfectly this characteristic pain and differentiates it from the pyloric syndrome, as well as from the solar syndrome); a vesicular sensitiveness which is increased by deviations from diet or rather by the use of certain fatty foods, fermented and distilled drinks, and still more by physical fatigue and moral troubles, sitting up late at night, gambling and sedentariness. The troubles are then exacerbated under the form of nausea, regurgitations, sudden pangs of hunger, pyrosis, swelling, meteorism. The pain irradiates in thoracic stitches in the side, palpitations with a bradycardic pulse and a gastrohepatic cough. Cryesthesia, subicterus, and emaciation are signs of hepatic deficiency, which is the prelude of cholelithiasis and degenerative lesions, implying the ineluctable necessity

of a cellular reparation by the physical agents, without prejudice to hepatic medication (of which we shall speak) and to the special treatment of the supposed cause (alcoholism, syphilis, infection).

Cholesterine constituting the greater part of the biliary stones and originating (according to the theories of your Austin Flint) in a disassimilation of the nervous tissue, and one understands how these concretions follow readily cerebrospinal perturbations and consequently require a radically etiological treatment: physiotherapy.

Hepatic congestion and hepatomegalia often accompany gastroenteritis and dilatation of the stomach, thus connecting themselves with that diathesis of autoinfection which characterizes cholemia and prepares chronic angiocholitis. The liver extends over the false ribs. It presents in its totality an abnormal sensitiveness, often irradiated in thoracic or dorsoscapulary stitches.

Cholemia expresses itself by subicterus, freckles, intestinal disorders (enteritis, appendicitis). Again physiotherapy is most efficacious for the cellular debility of these heredohepatics and will get rid of their symptoms of latent lithiasis due to gravel or biliary mud. For this work of functional renovation, diathermy will be the best treatment to employ and will best break the vicious circle of subintrance, lithiasic attacks.

Evidently, biliary stasis and lithogenous catarrh always remain the two great pathogenic causes of the gallstones. But, since MacCarthy, in the Mayo Clinic, demonstrated that these concretions may originate in the wall itself of the gallbladder (strawberry cells), it is still more rational to suppose that the physical agents, applied directly to the gallbladder, will exercise a curative and preventive action on the lithiasic evolution. Indeed, under the influence of high frequency and radiotherapy, large quantities of biliary gravel are frequently seen to evacuate from the swollen and painful vesicles.

The liver, said Bichat, is the regulator of alimentary hematosis, as the lung is that of airy hematosis. That is why a strict alimentary diet is required for sufferers from lithiasis.

Diathermic currents will more often prevent relapses of lithiasis than hydromineral alkaline cures (which are frequently unbearable to persons suffering from sclerosis, hypertension, and renal impermeability). Under their influence, epigastralgia, latent constrictions, visceral cramps, miniatures of the confirmed colic, will disappear: and the disaggregation of choleliths, their sandy dispersion will manifest themselves, generally after a few séances. I advise, at the same time: vibrotherapy, thoracic faradization and respiratory gymnastics, acting profoundly by the means of ozonized inhalations, convinced that I realize thus, by proximity the direct massage of the vesicular, congested and atonic region.

Mechanotherapy can also remove gravel, especially when one has recourse to the active and passive movements, imitating rowing, swimming, fencing, riding, which are known as the most capable exercises of mobilizing an inert lithiasis.

Semipenetrating röntgen rays, acting at the same time on the nervous system, on the motility of the smooth fibres and the biliary hypocrinia, cause the disappearance of those profound contusive pains, which signalize angiocholitis and are the terror of physicians and patients. Finally we must consider high frequency and the ultraviolet rays to exalt peristaltism and equilibrate the biligenic, antitoxic, and glycogenic functions. Thanks also to their cytologic power, these physical agents can prevent the coagulation of the mucus, which plays the most evident part in the agglomeration of gravel.

All these methods by no means exclude the pharmacotherapeutic agents approved by tradition and daily experience. I have besides observed that electricity constantly reinforces medicinal actions.

There are hepatic attacks which are purely nervous and independent of all gravel: hepatalgia, frequent in women and coinciding fairly often with hepatoptosis. To cure these pains which are sometimes violent (but always exempt from icterus, which distinguishes them from the real calculous colics), it is sufficient to have a few sittings of röntgen rays, galvanofaradism or high frequency effluves.

The vagosympathetic disequilibrium plays a great rôle in bringing on the spasm of the hepatic colic. The infection of the vesicle and of the pericholecystic peritoneum only manifests itself after the neurovegetative instability of the hepatic system. By modifying this "motor neurosis of the biliary ducts" (Chiray), physiotherapy calms and efficaciously prevents every painful paroxysm.

CIRRHOSIS

The atrophic or venous form of cirrhosis is closely connected with alcoholism. It is an ethylic intoxication of the cell, starting usually with gastroduodenitis and prepared, too, undoubtedly, by certain constitutional defects: arthritism, tuberculosis, syphilis. The hypertrophic or biliary form of cirrhosis is oftener only a premonitory period of the hardening and shrinking of the glands by the sclerous atrophic process.

Extreme lassitude, somnolence, incapacity for physical and intellectual work, hypochondria, general pruritus, pains under the right false ribs, development of varicose veins and hemorrhoids, couperose (brick red color), hemorrhagia: all these symptoms insidiously proceed splenomegalia and hydropsy ascites. The urine becomes scarce and charged with urates. The gait is hesitating and difficult.

From the first symptoms, high frequency effluves and diathermy should be applied with a milk diet and cholagogues, against slow and insidious prodromes. Let us not wait for pronounced deficiency, degeneration of the noble cells, proliferation in pronounced furrows, of the fibrous and conjunctive tissues: in the absence of an absolute anatomical reintegration, psysiotherapy is able to furnish these cells with a better functioning, giving the patient a sort of supplementary liver, and removing from him circulatory deficiencies and the dangers of oliguria. As a remedy for abdominal venous obstruction, calomel, sulphate of soda, iodides in small doses, will render great services, with a vegetarian milk diet and especially complete absence of alcoholic drinks.

Among the physical agents, diathermy is most indicated: the cellular exaltation which it excites awakens the most useful defensive reactions by the stimulating of the vasomotor nerves, equilibration of the portal tension, globular regeneration of the blood,

and restoration of physiological tonicity to the abdomen. The peritoneal adherences, boat shaped abdomen, ascending, canicular infections, obstruction by parietal thickening, of the choledochus and hepatic canal, represent so many tangible indications of diathermy. It increases diuresis and keeps off ascites, which is not solely due to the mechanical compression of the vena cava; it reestablishes normal stools and cures functional congestion, by exercising on the circulation of the gland a beneficent regulatory action, which aids the compromised hepatic cell. All these benefits are obtained thanks to an application of electric thermality of about 40° C., which in every visceral sphere creates an incomparable euphoric well being.

To hinder the process of conjunctive hyperplasia and to liberate thus the noble oppressed elements: such is the end attained by all the physical agents, which are all stimulants of cellular vitality. In a disease where the infectious element is known to play the greatest part, physiotherapy always solicits disintoxication. But it is certainly diathermy which shows the most selective action on the liver. The practitioner should count on it, without abandoning, however, the other numerous and varied engines in the physiotherapeutic arsenal.

HEPATIC HYGIENE

This particular hygiene should nearly always strive against hypohepatia, which is the rule in the proceeding pathological conditions and which presents itself with the common symptoms of general dysfunction, emaciation, anorexia, atonic and nauseous dyspepsia, a bitter taste in the mouth, alternating diarrhea and constipation, urobilinuria, discolored stools, icterus or subicterus, glycemia, insufficiency of urea, and other symptoms.

Open air exercise, vibrotherapy, mechanotherapy, sports and hydrotherapy, moderately directed, form part of the general hygiene of a hepatic patient. I am a great partisan of methodical respiratory exercises, which develop pulmonary ventilation and favor the venous circulation. In my opinion, the electric ozonized inhalation realizes the ideal of these gymnastics, whose slow and deep movements, execute by means of the diaphragm, a sort of automassage of the liver, precious against hepatic insufficiency, passive congestion of the gland, precirrhosis, which exists as well as prelithiasis or biliary gravel: an excellent method for fighting against the functional deficiency of the cell and regulating secretions and incretions.

We must avoid intellectual and moral overwork, worries, grief, various emotions, noted since ancient times to have always a fatal repercussion on the liver.

Let us remove from alimentation dishes rich in cholesterine and purines which favor uricemia. For meals, let us recommend regular hours and a thorough mastication: no condiments or stimulants. Let us always associate the use of calomel, castor oil, and salicylate with the physical treatment.

Calomel manifests an elective action on the liver, both on the torpid and on the erethic one. It is an excellent hepatic medicine, acting on biliary obstruction and portal stasis. A marvellous antiseptic and intestinal antitoxic, and a mercurial chloride, it solicits a salivary and pancreatic hypercrinia which contributes as much as the biliary hypercrinia, to the hepatointestinal detersion. It destroys neither diastasis nor useful ferments, ameliorates the renal epithelium and combines its diuretic rôle with its disintoxicating power, which denominates the notable diminution of the sulphoconjugated acids in the urines: that is why venous stasis, edema and ascites are favorably influenced by calomel.

Castor oil, an excellent, intestinal derivative, purging quickly and without colics, completes and perfects the eccoprotic action of calomel.

Salicylates, given in small doses, act like antiputrides promptly eliminated, fluidizing the bile, increasing the urea and diminishing uric acid, by removing from the economy a notable proportion of glycocoll.

The curative results of medicaments, calomel, castor oil, salicylate of soda, are much more complete (as we have often shown) when (with the aid of diathermy, ultraviolet rays and other physical agents) we try at the same time to decongest, deobstruct, and revive the gland and act electively on the solar plexus, which has the chief command over its vitality. Everyone knows that icterus may show itself suddenly, by the nervous contraction of the excretory ducts of the bile: this spasmodic icterus can be rationally treated by diathermy and electric radiations, which overcome dysfunction and restore the biliary flow to its normal condition.

Let us add that physical therapy is particularly efficacious against arthritism and diseases of nutrition; if it cures daily, rheumatic, gouty, obese, diabetic, asthmatic, eczematous and nervous patients, it is by the intermediary of the liver, the generator of these proteiform diathesis. In acting on the liver, our methods restore all the physiological perversions, for the hepatic rhythm, broken or deviated, creates in the end, or confirms by persistence, the most serious organic lesions.

SUMMARY AND CONCLUSIONS

1. The functional deviations of our enormous gland, the liver. are, for us, the dominant causes of the acute diseases and chronic conditions mostly observed in practise.

The bile which we consider to be composed of the majority of the excreta of the organism, plays a considerable part in clinical medicine. Its lack of normal elimination by way of the intestines is the chief cause of all disorders in health.

The liver is really, by its volume and the importance of its function, a veritable laboratory of life. Its deficiency or functional deviation creates a morbid condition.

The perfect integrity of the *defecatory* function of the liver is indispensable to nutritive mutations and organic equilibrium.

2. The clinical symptoms of hepatic deficiency (or torpid liver) are of a fundamental importance in practise, and the rational treatment of dyshepatias represents the most important of prophylaxis. We assure the success of chemical medications (calomel, salicylate, carbonate of soda) by combining with them, the renovating action, cellular and nervine regenerator, attributed to the specialized, or better associated physical agents, principally diathermy or electrothermopenetration combined or not with actinotherapy and vibrotherapy.

3. The combined treatment prevents and cures the

common manifestations of cholelithiasis, its complications and allied conditions. If we act in the period of cholelithiasis, we shall more often avoid the painful attacks of hepatic colic and the dangers of infectious angiocholitis. A strict alimentary hygiene, cholagogue medication and physiotherapy constitute here the therapeutic triad. Among the physical agents, hepatic diathermy, vibrotherapy, faradization, the ozonous inhalation, mechanotherapy, and at times high frequency, the ultraviolet and x rays should be employed. For their precision and curative energy, a special place should be given to the diathermic currents. All these agents cure, by activating biliary excretion, remedying the vagosympathetic disequilibrium, stimulating and restoring the deviated nervism.

4. The hepatic appanage of alcoholism, cirrhosis, is a proliferation of conjunctive tissue, whose sclerotic tractus destroy and degenerate the noble cells of the liver. We must not wait for the trophic processes to be too far advanced, to apply an efficacious treatment to cirrhosis. The milk diet and certain hepatobiliary medications, exalting the defensive reactions of the cell, find in diathermy and in the other physicotherapeutic agents the adjunct to a beneficent struggle against the fatal conjunctive hyperplasia, and for the liberation of the oppressed anatomical elements of the hepatic gland. The infectious syndrome, which is always more or less mixed with cirrhosis, is at the same time neutralized by heat, light, electricity, movement and radioactivity, etc.

5. The hepatic hygiene consists above all in preventing hypohepatia, the functional diminution of the organ from the first cholemic symptoms (modern cholemia is nothing else than the ancient bilious temperament). All the physiotherapeutic modalities may here be employed, at the same time as a strict alimentary régime, laxatives and cholagogues, calomel, castor oil, salicylates and alkalines.

Some Interesting Surgical Procedures with High Frequency Electric Currents*

GRANT E. WARD, M.D.
Baltimore, Md.

Surgical electrothermic methods are generally employed in treating malignancy, but I find the high frequency current of great value in some other conditions as well. It is my purpose to describe briefly a few of the electrothermic methods applicable as an adjunct to the surgeon's armamentarium. I omit all discussion as to the types of currents and the apparatuses generating them, as they have been previously discussed (1).

Radical resection of the inferior maxilla.—I include a description of an operation for resection of the inferior maxilla for advanced malignancy in order to illustrate the tremendous field for extensive operations without the scalpel and with but few or no ligatures, while at the same time throwing a barrier of coagulated tissue around the growth against any implantation of viable cells and metastasis through the lymph and blood streams. The technic of establishing this line of coagulation around and under the growth, prior to removal, has been developed by Clark and Wyeth, and is termed circumvallation by Kelly. I redescribed this technic in the above mentioned article, and employ it constantly in removing malignant tumors. In the case under consideration the patient had an advanced squamous cell carcinoma of the lower jaw, extending from one mandibular angle across in front to the other angle, and invading as well the floor of the mouth and undersurface of the tongue, reaching down to the hyoid bone. Most of the chin had sloughed away, and there was involvement of a large portion of the skin covering the jaw. Fortunately, there were no palpable metastatic glands. The patient had had previous radium treatments, curettings and partial operative resection.

After heavily implanting the disease with glass radium emanation seeds, I resected the jaw under interrupted ether anesthesia, and with an almost bloodless procedure, tying but three vessels, one at each angle of the inferior pillar of the fauces with the tongue, and the third lower down in the right side of the neck. The line of coagulation circumvallating the growth extended from the angle of the mouth on the right side, back to the angle of the jaw, through the bone and down into the neck, then anteriorly to the midline of the neck just above the hyoid bone. A similar line of coagulation was carried from the left angle of the mouth through the cheek to the angle of the jaw, then down to the neck and anteriorly to meet the line from the right side. As the more effective acusector (endotherm knife of Wyeth) was not then available, a scalpel was used to cut through the line of coagulated tissues. The depth of coagulation was from five to ten millimetres; greater penetration would have been possible by stronger currents applied for a longer time with the needle inserted further into the tissues. After cutting through the line of coagulation, a new advance line was laid at a deeper level, and so on until the jaw was amputated. The bone was treated with the high frequency bipolar current, and cut through with a rongeur; it yielded much more easily after treatment with the current than live bone.

There was no pain in the convalescence, and no secondary hemorrhage. Under dressings saturated with sodium hypochlorite, healthy granulations promptly sprang up, and the patient soon presented an entirely different appearance. Whereas the whole lower jaw was a sloughing offensive cancerous mass, the wound was now fresh and clean and the patient far more comfortable. The tongue was held up by bandages around the head so that liquid foods were taken readily and the patient lived in comparative comfort for the four remaining months of his life.

*The Howard A. Kelly Hospital, Inc.

Fig. 1.—Radical resection of the inferior maxilla. View of left side of face.

Death was probably due to malnutrition, as there was no evidence of internal metastases. Recurrences appeared beneath the tongue close to the hyoid bone, and along the left cheek, which were treated by the implantation of radium emanation seeds and local applications of radium emanation.

This operation illustrates how extensively high frequency currents may be employed in advanced malignancy in cleaning up nasty sloughing areas, and giving comfort to the sufferer. Such an example demonstrates *a fortiori* how much can be done in all lesser degrees of advancement to save lives not to be helped in any other way, and is surely an occasion for rejoicing.

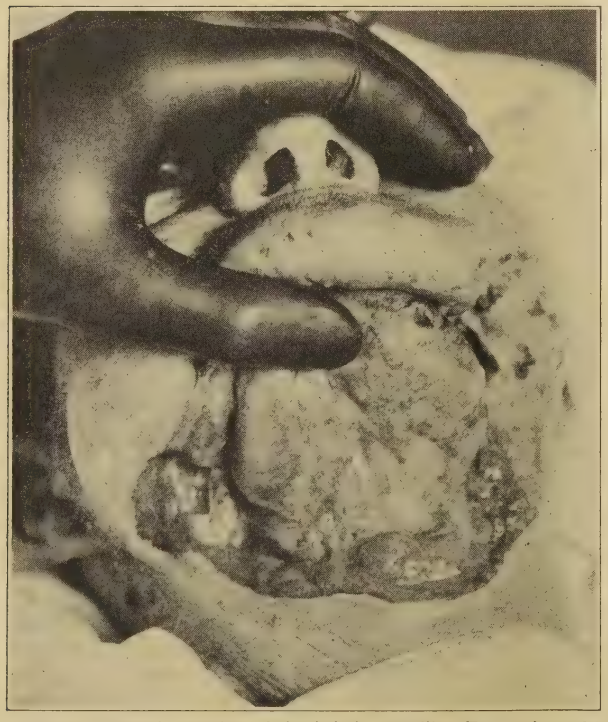

Fig. 2.—Radical resection of the inferior maxilla. Front view with tongue held up. Note healthy granulations which quickly spring up after electrothermic operations.

Hemostasis without suture.—In this Journal (2) I previously described a technic for hemostasis without suture which I here illustrate again to emphasize its value in extensive operations as described above. Occasionally large bloodvessels are opened in spite of the coagulated tissues through which the incision is made. These are caught at once with clamps and coagulated by applying the current through the hemostats one by one.

This method is of special value in opening the abdomen or removing the malignant breast as described by Howard A. Kelly (3) and the author. The accompanying photograph (Fig. 5) is of the first patient on whom a radical breast operation was done

Fig. 3.—Radical resection of the inferior maxilla. Front view with tongue dropped.

without any ligations. Hemostasis was secured by the clamp coagulation method. We have adopted the safer policy of tying the primary branches of the axillary vessels but coagulating all others.

Surgical treatment of epithelial lined cavities.—High frequency currents play an important part in the surgical treatment of epithelial lined cavities. This field was opened by an interesting and successful operation for a ranula, described by me (4). The patient, a young woman, was operated upon under local anesthesia, and spared the prolonged hospitalization necessary after a more radical operation. The cyst was opened anteroposteriorly with the acusector, and the epithelial lining destroyed by desiccation with the monopolar current. The almost invisible scar allows perfect function.

Some weeks after this, I was associated with Dr. Kelly in a laparotomy for pelvic disease on

FIG. 5.—Patient upon whom a regular breast operation was performed without ligations. Hemostasis was secured by clamp coagulation.

a patient who also had a large postoperative hernia. After completing the pelvic operation, the hernial sac was severed from its junction with the intraabdominal parietal peritoneum, and the abdominal cavity closed. To resect the sac with the scalpel involved a tedious, bloody procedure. The operation was therefore completed by destroying the epithelial lining of the sac with a monopolar current, following the technic used in treating the ranula. The fascia layers were then brought together and the wound closed as usual in repairing a postoperative ventral hernia. The

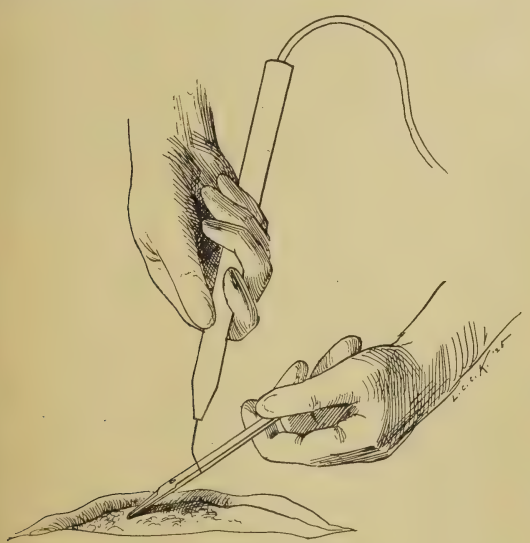

FIG. 4.—Hemostasis without suture.

patient made an uneventful recovery without infection, and the thin layer of desiccated tissue was evidently readily absorbed. Here an awkward, prolonged operation was converted into a simple one, and the duration of anesthesia and consequent risk lessened.

Recently Dr. Kelly has employed this treatment of epithelial lined cavities in small benign cysts of the ovary. While operating in the pelvis for other disease, small bilateral cysts of the ovary were encountered, opened, evacuated, the cyst wall desiccated with a monopolar current, and the cavity obliterated with a fine catgut suture, replacing the longer and more bloody resection of the ovary, while preserving all of the normal ovarian tissue.

Rectal polyps.—The bipolar damped high frequency current is invaluable in removing single or multiple polyps of the rectum, an operation accompanied by little or no bleeding, employed by William L. Clark for some years in bladder papillomas.

If the tumor is small, the operation can be done

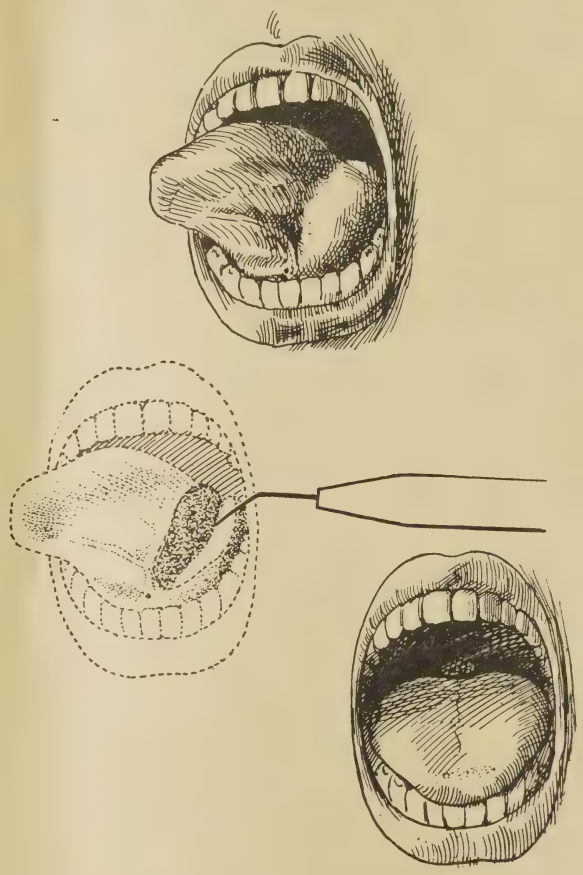

FIG. 6.—Ranula treated by incision with acusector and desiccation of epithelial lining. Perfect result.

through a cylindrical proctoscope, preferably of hard rubber or glass, with the patient in the knee chest posture. A tonsil snare is thrown around the pedicle of the tumor, and the current applied to the metal handle of the snare. As the pedicle is coagulated, the snare is slowly tightened so as to cut through the base. The tumor drops off, leaving a white dry surface. In treating massive tumors, the patient takes a general anesthetic in the lithotomy position, and the rectal sphincter is thoroughly dilated and the mass exposed by an insulating cylindrical proctoscope, or with a bivalve rectal speculum. Frequently the tumor is made more accessible by lateral vaginal retractors. In a recent case the rectum and ampulla were choked with the papillomatous growth, springing from a number of areas. Twelve large pieces were removed, showing papillary carcinoma. Some of the polyps

were too large to be engaged in the loop of the snare. These were attacked piecemeal by snaring off separate portions. In case of malignancy, a plaque containing radium emanation tubes should be applied to the base of the growth after removal, and a dose of thirty to forty millicurie minutes given directly to each area of an inch and a half in diameter, while carefully protecting the surrounding normal rectal mucosa. Healing takes place promptly following separation of the slough which comes away in from five to seven days after the operation. The scars are soft and pliable, and there is no postoperative pain.

SUMMARY

1. High frequency currents properly used surgically are of great value in relieving patients having extensive malignancy of the lower jaw.

2. Hemostasis may be secured by the clamp coagulation method without the use of foreign ligature material.

3. Epithelial lined cavities, as ranula, postoperative hernias, and benign ovarian cysts, are effectively treated and closed without long difficult dissection.

4. Rectal polyps can be cleanly removed by tonsil snare coagulation with little if any bleeding, and with less likelihood of recurrence and metastasis.

Ultraviolet Therapy in Pediatrics*

EDWIN T. WYMAN, M.D.
Boston

Ultraviolet rays in the treatment of many diseases of infancy and childhood are now recognized as a very valuable therapeutic measure. Direct sunlight is probably the most effective way of giving this form of treatment.

Our knowledge regarding the sun's rays has been materially advanced by scientific investigations during recent years. It has been found that the rays of light which may be referred to as the healing or curative rays, lie in the ultraviolet zone. It has been found also that these ultraviolet rays in the sun's spectrum vary in intensity during the different seasons of the year being highest during the summer months and lowest during the winter months. It is believed that this seasonal variation is due to the absorption of the shorter wave lengths by the atmosphere. In any event, it is evident that from a therapeutic point of view, the determining factor is the quality not the quantity of these short or ultraviolet radiations.

Here, in New England, during the warm summer months it is possible to use direct sunlight in treating infants and children. It is impracticable to expose an infant to the direct rays of the sun and it is inadvisable to expose older children during the fall, winter and spring months on account of the cold and consequent loss of body heat. This difficulty, however, may be overcome by the use of a quartz window or a glass which is transparent to ultraviolet rays so that the baby can have its sun treatment in a warm room. There are two such glasses on the market at the present time, Lamplough's vitaglass, an English product, which the manufacturer asserts transmits the actinic rays to the extreme limit of the sun's spectrum 290 millimicrons, and a new ultraviolet transmitting glass which is manufactured in Corning, New York. This latter glass, the manufacturer states, transmits to two hundred millimicrons in three millimetre thicknesses. Its transmission for wave lengths of 290 millimicrons, the extreme limit of the sun's rays through the atmosphere, is eighty-six per cent. through a two millimetre thickness (uncorrected for surface reflections) as measured by the Bureau of Standards. For purposes requiring a full transmission of ultraviolet light from the sun, therefore, this glass is practically the equal of clear fused quartz. The cost of producing this glass is somewhat above that of window glass but is far below that of quartz. If this glass is all that it is stated, it should be ideal for nursery windows where the baby can have its daily sunbath, for hospital windows and a number of possible applications for the use of ultraviolet light in the sun's rays. However, during the winter months in New England, it is questionable whether or not there are sufficient ultraviolet rays in the sun's spectrum to be of much therapeutic value, although, our experiments, not yet published, tend to make us believe that the sun's rays through a quartz window are of definite therapeutic value even during the winter months.

When direct sunlight is used, we use the following scheme of exposure:

INFANTS

The sun bath can be given in a room with the sunlight coming through an open window, on a veranda or sunporch, or in the shelter of a garden or yard. If given in the open the infant should be protected from the wind by a cloth screen on three sides. A sheet draped on three sides of the crib will do, although, it is better to have the shelter four or five feet high. On cool days the hands and feet should be kept warm by means of mittens and socks, and a hot water bottle or an electric pad can be used to maintain the body heat. By means of an open window or door, the bath can be given in a warm room, free from drafts. In starting the treatment the infant should wear a diaper, band and shirt. The head and nape of the neck should be protected from the direct rays of the sun by a sunshade, cotton hat,

*Read before the First Annual Meeting of the New England Association for Physical Therapy, Boston, October 26, 1925.

or a sheet draped over the head of the crib. During July and August the bath should be given between 8 and 10 a. m., or between 2 and 4 p. m. In June and September it should be given in the middle of the day. At the start the baths may be given two or three times a day, and, as the length of exposure increases, the number of baths are gradually decreased to one or two a day, depending on the complexion of the patient and the intensity of sunlight.

Scheme of exposure:—The legs and lower thighs are exposed to the direct sun's rays for five minutes, front and back. The exposure is increased five minutes, front and back, each day until on the third day the legs and lower thighs are exposed for fifteen minutes, front and back. On the fourth day the diaper is removed after the legs and thighs have been exposed for fifteen minutes and a total exposure of twenty minutes is given to the front; then the diaper is replaced and the exposure is repeated to the back. The exposure is increased five minutes each succeeding day until on the sixth day a total exposure of thirty minutes is given to the front and to the back. On the seventh day the diaper is removed after the legs and thighs have been exposed for fifteen minutes; then, after a total exposure of thirty minutes, the band and shirt are removed and the exposure continued for five minutes longer until a total exposure of thirty-five minutes is given to the front. The diaper, band and shirt are replaced and the exposure repeated to the back. On the succeeding days this same scheme is followed, increasing the total exposure five minutes each day until on the twelfth day a total exposure of sixty minutes is given to the front and to the back. On the following days the diaper, band and shirt are removed five minutes earlier in the exposure each succeeding day so that on the fifteenth day the diaper is removed at the beginning of the bath and the shirt and band are removed after fifteen minutes exposure. On the eighteenth day the diaper, band and shirt are removed at the beginning of the bath and a total exposure of sixty minutes is given to the front and sixty minutes to the back. After the eighteenth day general exposures of one hour to the front and one hour to the back are given.

CHILDREN

The same scheme is used with children. First the legs and thighs are exposed, then the abdomen from the ribs to the hips, and last the chest.

This scheme shows the usual progression in normal cases; it does not represent a hard and fast rule and can be varied depending on the general condition of the patient, the tolerance to sunlight, temperature and wind, height of the sun and clearness of the atmosphere. It is better for patients whose skin burns very readily to take shorter treatments, three or four a day, to more gradually accustom the body to the sun. Many patients with dark skins can withstand twice the exposure given in the table. The whole object of the scheme is to get the patient well tanned without sunburn.

At present during the winter months and on cloudy days in summer, it is necessary, in treating infants, to use a substitute for sunlight. The mercury vapor quartz lamp at present surpasses all other sources in ultraviolet efficiency and is the best means of artificially producing rays similar to the short therapeutic rays in the sun's spectrum. The sun's spectrum ends abruptly at about 296 millimicrons, due to the absorption of all shorter wave lengths by ozone in the atmosphere. The mercury vapor quartz burner emits ultraviolet radiation, consisting of a continuous spectrum between 185 and 400 millimicrons, upon which is superimposed the mercury arc line spectrum, the principal lines of which are at 364, 313, 302, 280, 265, 240, 200 and 185 millimicrons. There are many other lines, but those mentioned above are the most intense. The two lines 265 and 255 are especially strong. The line 364 is the strongest line of the mercury ultraviolet spectrum. Experiments (1) with light filters in irradiating cholesterol solutions seem to show that rays of 302 millimicrons or less are necessary to confer antirachitic property.

There are three American mercury quartz lamps on the market. The Alpine sun lamp, the Burdick lamp and the Victor lamp. Both the Burdick and Victor lamps have the same burner, the Cooper-Hewitt uviarc.

We are now using Alpine sun burners in the outpatient department and medical wards of the Children's Hospital when individual treatments are given. In the Infants' Hospital, we are using a room with four Burdick lamps suspended near the ceiling, arranged to give as even a distribution of light as possible over the cribs. This permits us to treat a number of patients at the same time. The room contains ten cribs. The individual treatments are given with the lamp at a uniform distance of twenty inches from the surface of the body. The entire surface of the baby with the exception of the head is exposed. The head is protected by a sheet draped loosely over the head of the crib, or, when a table is used, the sheet is draped over a farmework on the treatment table, coming down over the baby's neck. The front and back are given the same exposure. The patients are divided, because of the variation in skin tolerance, according to their complexions, light, medium, dark and black. When individual treatments are given with the Alpine sun burner, the light complexioned patients are started at two minutes exposure, front and back, and the time of exposure increased two minutes, front and back, each treatment, until the total exposure of twenty minutes, front and back, is given. The medium complexioned patients are started at three minutes exposure, front and back, and increased three minutes, front and back, until the total exposure of twenty-five minutes, front and back, is given. The dark complexioned patients are started at four minutes, front and back, and increased four minutes front and back, until a total of thirty minutes, front and back, is used. The black or negro babies are started at five minutes, front and back, and increased five minutes, front and back, until a total of thirty-five minutes, front and back, is given.

In the light room of the Infants' Hospital, equipped with four Burdick lamps suspended from the ceiling, having a vertical tube distance (from the patient to the burner) of seven feet six inches, the same method of exposure is used as with the individual treatments, except that the total exposure of the light complexioned patients is increased to thirty minutes.

front and back, the medium complexioned babies to a total of forty minutes, the dark compexioned patients increased to fifty minutes and the black or negro patients' exposure is increased to a total of sixty minutes, front and back. The ward patients are given daily treatments while the patients coming in to the out patient department are given treatments three times a week. This method of treatment is used in all types of cases. The time of exposure has to be shortened occasionally on account of a very delicate skin. The time given above for individual treatments with the Alpine sun burner is longer than should be used when new burners are employed as the efficiency of our burners has diminished with length of service.

RICKETS

Rickets occurs universally in northern civilized countries, such as Europe and North America, where there is lack of sunlight during the winter months. The seasonal variation in the recurrence of rickets offers striking evidence of the part sunlight plays in the prevention of the condition. Rickets flourishes generally under poor hygienic surroundings, and especially under conditions where direct exposure to the rays of the sun is infrequent or entirely absent. Rickets can be cured both clinically and in experimental animals with certainty by the administration of cod liver oil. It can also be cured with certainty by the action of ultraviolet light.

In 1923 a special clinic for the treatment of rickets with the mercury vapor quartz lamp was started in the out patient department of the Children's Hospital, Boston. This clinic has been carried on since that time, except during the summer months when the patients are given daily sunbaths at home in place of the Alpine lamp treatments. In this time, we have treated about two hundred cases of rickets (varying in severity) with universal success. We concluded after treating a number of rachitic patients with ultraviolet irradiation and a number of rachitic patients with both ultraviolet rays and cod liver oil, that the combination of cod liver oil and ultraviolet light probably hastened the healing process more than either ultraviolet rays or cod liver oil alone. At present, we are treating the moderate and severe cases of rickets with both ultraviolet irradiation and cod liver oil. The mild cases are treated with cod liver oil alone, as it seems unnecessary to have the patient make extra trips to the hospital for light therapy. The length of time required to cure severe cases, as shown by röntgenograms and the serum calcium and phosphorus concentration, is from six to eight weeks. They are then discharged from the "light clinic" and cod liver oil is continued to prevent a recurrence of the disease.

SPASMOPHILIA

Spasmophilia is a nutritional disease characterized by convulsions, carpopedal spasms, laryngismus stridulus and an extreme irritability of the nervous system to mechanical and electrical stimulation. The blood chemistry shows a low serum calcium concentration. It has been made quite clear that all cases of infantile tetany have rickets, but all patients with rickets do not have tetany. To treat an established spasmophilia one must use measures that will increase the blood calcium rapidly and permanently. Ultraviolet therapy has been shown to exert a favorable influence in tetany. These rays not only influence the symptoms favorably but the symptomatic relief is paralleled by a return of the calcium concentration in the blood serum to normal. The treatment followed at the Children's Hospital is to give calcium chloride, ten to twenty grains three times a day, in addition to ultraviolet irradiations. The result has been uniformly good. If rickets is present to a marked degree, as is often the case, the treatments are continued until the rachitic processes are healed. After the patient is discharged from the light clinic, cod liver oil is continued to prevent the recurrence of rickets, and calcium chloride is continued for a time to prevent the recurrence of tetany. The time required to cure the average case is from ten days to two weeks.

TUBERCULOSIS

Gerstenberger and Wahl (2) and others found the ultraviolet ray of decided value in the treatment of peritoneal, glandular and osseous tuberculosis. They think that of the glandular forms the mesenteric was most rapidly improved; next the mediastinal and last, the peripheral. Beneficial results were not obtained in pulmonary tuberculosis of the miliary type, although treatments were begun early. The patients we have treated for tuberculosis of the mediastinal glands and tuberculosis of the mesenteric glands have responded well to ultraviolet therapy. The treatments have seemed to improve their general condition, to relieve the symptoms, such as cough in the bronchial cases and abdominal pains in the mesenteric cases, and to favor early calcification of the glands. Our results in the cases of tuberculous peritonitis have been variable. It is not expected that ultraviolet therapy will cure all cases of tuberculous peritonitis. However, our cases show that it is a valuable therapeutic measure. We believe that it should be used unless there is marked febrile reaction. It is much more difficult, in treating tuberculosis and many other diseases with ultraviolet rays, to draw definite conclusions as to the benefits obtained from this form of therapy, because in rickets and tetany the blood chemistry and x ray give confirmatory evidence of recovery. One has to depend almost entirely on clinical findings to note the progress of the case and it is often difficult to tell how much the disease has been influenced by the rest, fresh air, proper nourishment and general hygiene given as routine treatment in addition to the ultraviolet rays.

PSORIASIS

We have observed marked improvement in all the patients treated for psoriasis while they received treatment.

FURUNCULOSIS

Our results with furunculosis have been favorable, although in most cases the improvement was no more marked than when the ordinary treatment was used. Some persistent cases, which did not respond to vaccines and local treatment, cleared up rapidly, however, with ultraviolet therapy.

ECZEMA

We have not found this form of therapy useful in cases of eczema, although in some instances, with ad-

ditional infection of the skin, the germicidal properties of the light helped to clear up the infection.

BRONCHIAL ASTHMA

We have used this form of therapy in a case of bronchial asthma in which the child has a sensitization to bacteria. After other forms of treatment had failed, ultraviolet irradiations had a most beneficial effect. The attacks have become less frequent and less severe and the patients were improved in all respects.

CONCLUSION

1. In conclusion it may be said that direct sunlight is a useful therapeutic measure in the prophylaxis and treatment of many diseases in infants and children.

2. With the development of glasses capable of transmitting ultraviolet irradiations it may be possible to have these windows in hospitals for treatment of infants and children during the winter months and also in every nursery so that the baby can have its daily sunbath in a warm room.

3. The mercury vapor quartz lamp can be used as a substitute for sunlight and has the advantage of being available regardless of sunshine and weather. It can be given indoors so that it will not subject the child to cold and the doses can be accurately gauged.

4. There is, however, a real danger of becoming too enthusiastic about ultraviolet therapy less this form of treatment be looked upon by the physician and his patient as a quick and sure cure for all ailments.

5. It can be said that ultraviolet therapy is a specific in the treatment of rickets and spasmophilia and is a valuable therapeutic agent in the treatment of tuberculosis of the mesenteric and bronchial glands and tuberculous peritonitis and is useful in psoriasis and some persistent skin infections.

Diathermy—Its Physics and Clinical Indications

RICHARD KOVACS, M.D.
New York

Due to the extensive and succesful application of physical therapeutic measures during and after the World War—when millions of men had to be put back into functional ability in the shortest possible time—the medical profession of America is showing considerable interest in the employment of physical therapy in the various departments of medicine. In response to this interest, manufacturing concerns are turning out an increased number of efficient apparatus and are pushing their sale by advertising and by the subtle force of the itinerant lecturer. The wholesale buying and employment of apparatus on salesmen's advice is, however, not going to insure the proper place and employment of physical therapeutics in the physician's armamentarium. Only the comparative and unbiased study of the various forms of physical therapy, the clear visualization of their nature and their mode of action on any particular pathological condition, together with the appreciation of the correct technic of application, will enable physicians to be truly progressive in this rapidly expanding field of therapeutics.

In order therefore to evaluate the place of high frequency currents in therapeutics we must first become acquainted with their relation to the other forms of therapeutic electricity. Electricity in the commercial world is used for three main purposes: for chemical action (electroplating); for mechanical action (driving of motors, dynamos); and for heating (coils in heaters, toasters, curling irons, etc.) In the human body, a similar grouping of the effects of electricity can be accomplished, according to the form in which electricity is applied. The determining factor will be whether the electricity as employed is of constant flow (galvanic) or alternates at low frequency (faradic and sinusoidal), in both cases of low tension, or whether it is of high frequency and of high tension.

Electricity of constant flow and low tension acts on the human body as a chemical substance (electrolyte) by causing definite action round and between its poles and the wandering of ions in the interpolar path. The action at the poles is stimulation and reflex irritation, due to improved circulation and cellular activity, besides each pole exerts a distinct caustic action, the positive pole (anode) being acid caustic and thus hardens tissue, stops bleeding and repels bases, while the negative pole (cathode) is alkaline caustic, softens tissue, increases bleeding and repels acids. An example of the polarity action of the galvanic current is its employment under the designation of electrolysis, for the removal of superfluous hair: a fine platinum needle connected to the negative pole is introduced into the hair follicle and the caustic substance formed around the needle will destroy the follicle. The interpolar action of the galvanic current is mild heat.

When the galvanic or constant current becomes interrupted or rhythmically reversed (sinusoidal current) over muscular parts of the body, gentle or vigorous muscular contractions are produced and this mechanical action is utilized for the treatment of muscular atrophy or paralysis or for tissue stimulation.

The faradic current is an irregularly alternating current and produces painful sensory stimulation of the skin and on account of the rapid sequence of the individual peaks of its flow, a tetanic contraction of normal muscles. It is used as an important diagnostic evidence that the nerve supply of a muscle is intact.

All these forms of electricity have only a relatively

superficial action of the human body; because of their polarity action, the muscular contractions and the painful sensory stimulation caused, they cannot be employed at sufficiently high tension (voltage) to penetrate deeper parts. d'Arsonval of Paris made the discovery in 1888 that an electrical current alternating less than fifteen times per second produced a succession of separate or clonic muscular contraction, at twenty to thirty per second a continuous contraction (tetanus) the intensity of which increases till a frequency of about three hundred is reached. A further increase of frequency causes a decrease in the strength of contraction until at a frequency of ten thousand per second absolutely no effect is produced upon either the motor or sensory nerves. The reason for this phenomenon is that with the extremely rapid changes in the direction of the current there is no possibility for the development of electrochemical reactions. High frequency currents travel through the body tissues as solid conductors, and subject to the laws of electrothermic reaction, produce heat within these conductors in proportion to their resistance. The patient has no other sensation except that of warmth, and this can be easily regulated from extreme gentleness to the cooking or destruction of tissues. All medical forms of high frequency currents are absoutely painless because they stay within the limits of physiological heat toleration of the tissues. When the same heat, however, is emplayed for the purpose of surgical high frequency or the destruction of tissues, the sensation of pain naturally returns and in most cases the employment of a local or general anesthetic becomes necessary.

PHYSICS AND CLASSIFICATION OF HIGH FREQUENCY CURRENTS

The essential parts of any high frequency apparatus are, 1, a supply of alternating current, either directly from the AC mains or the change of a direct current supply into an alternating one by means of a rotary converter; 2, a high frequency circuit, which raises the voltage or tension of the current by means of a step up transformer and its alternation or frequency by a condenser—spark gap arrangement. The patient is connected in shunt to the high frequency circuit and as at times his body offers less resistance to the high frequency current, than the internal resistance of the circuit itself, the part of his body included between the electrodes connected to the two terminals of the machine will be traversed by high frequency current.

There are three main types of high frequency machines in existence, 1, the older type of d'Arsonval, in which currents of relatively high voltage (tension), of relatively low amperage (volume) and of intermittent and dampened oscillations are produced. Such currents exert a general systemic effect, increase metabolism, lower the blood pressure, but produce only a moderate amount of local heat. They are properly called "currents of tension" but can be disregarded from the practical standpoint of this paper; 2, modern apparatus furnishing diathermy type of currents, which are of relatively low voltage, of high amperage and of sustained and dampened oscillations. Such currents exert a very marked amount of local heat and are called "currents of quantity" or diathermy; 3, the latest developments are machines producing undampened oscillations by a radio bulb apparatus or other arrangement, furnishing a "cutting" current for eminently surgical purposes.

Either of these three types of machines can be used for either medical or surgical action, i. e., local or general stimulating or local destructive action, and can be applied either from two terminals or one special terminal, i. e., in form of a bipolar or monopolar application. An elaborate and for the beginner decidedly confusing terminology has been built up to signify all these varieties but in this short presentation we will confine ourselves to some of the details of the second type of currents; the diathermy currents.

PHYSICS OF MEDICAL DIATHERMY

The modern diathermy machine, producing oscillations of one to two millions per second at a comparatively low voltage, makes it possible that currents from five hundred to three thousand milliamperes are driven through the tissues of the body without any other sensation than that of heat. The body tissues act as solid conductors in such event, and there are definite measurements available as to the conductivity of animal tissues to electrical currents. According to Alt and Schmidt if the conductivity of muscle and blood is 1,0, the relation of other tissues is as follows: nerves 0,17, skin 1,25, brain 1,57, tendon 3,25, fat and fascia 3,92, bone 14,1. The degree of heat produced will depend on the following factors: 1, The strength of the current; 2, the size of the electrodes. The same current will produce a higher temperature under a small than under a large electrode, because its density will be greater in the region of the small electrode. We utilize this fact to localize the maximum amount of heat at will at any plane between the electrodes by varying their size. With electrodes of equal size properly applied, the maximum amount of heat will be half way between the electrodes; 3, the type of tissue traversed, as according to Jouloes law the heat developed in a conductor is in direct proportion to its resistance. Ordinarily, however, the diathermy current will travel by the way of the less resistant tissues. If, for instance, the current is passed longitudinally through a limb, it will heat up the less resistant soft parts especially the bloodvessels, and have comparatively little effect on the deeply situated bony structures. If we want to heat these we must pass the current transversely through the joint, so there should be no path of less resistance open.

PHYSIOLOGICAL EFFECTS AND INDICATIONS FOR MEDICAL DIATHERMY

The local effects of diathermy are based on the fact that heat is generated within the tissues. Such heat is much more effective than heat obtained by means of conduction as by hot applications or by convection as by radiant light and heat, which merely heats the surface.

Heat applied externally cannot penetrate deeply, 1, on account of the skin resistance; 2, on account of the circulating blood, which as part of the heat regulating mechanism of the body will tend to distribute any excess of local heat evenly all over the organism. The heat of diathermy is produced within the tissues

by the transformation of electrical energy into thermic energy, and is produced faster than the heat regulating mechanism can dissipate. Experiments by many investigators have shown that the human tissues can stand up to about 116 to 118° F. of heat without damage. Cumberbatch found that the sensitive female urethra will tolerate up to 113° of heat, while in the cervix 120° heat can be produced without discomfort. Clinically we gauge the heat produced by the hot wire milliamperemeter and can control it to the finest degree.

The clinical action of diathermic heat can be classified in four main groups:

1. Active arterial hyperemia and hyperlymphia, which increases both the local and general body metabolism. Inflammatory exudates become disintegrated, resorption is promoted. Diathermy is accordingly indicated in a very wide range of traumatic and inflammatory conditions as in sprains, strains of joints, traumatic and ordinary myositis in both acute and chronic varieties. Most forms of arthritis respond to diathermy. Complications of fractures, painful or exuberant callus, persistent edema are favorably influenced. As diathermy can be successfully localized into any of the internal organs, there is an ever widening field of its employment in pneumonia, bronchitis, pleurisy, in chronic adhesions, inflammations of the stomach, gallbladder, and the intestines. Many favorable reports have been received in gynecological conditions, diseased adnexa, perimetritis and parametritis, as well as in inflammations of the male organs, prostatitis, epidydimitis. Eye, ear, nose, and throat men are becoming increasingly interested in the possibilities of the penetrating heat effects of diathermy.

2. Local relief of pain is the second main action of diathermy and this is likewise infinitely more pronounced than the sedative action of the more superficial forms of heat application. This can be explained by the deeper action on all nerve endings of the affected area. Many forms of neuralgia, myalgia, arthralgia, yield favorably. On the other hand in cases of referred pain diathermy will be disappointing. The analgesic action adds to the favorable influence of hyperemia in many acute inflammations. Attacks of angina pectoris have been rapidly relieved, the insomnia of neurasthenics, the lancinating pains of tabetics benefitted.

3. Antispasmodic action (specially emphasized by Kowarschik and de Kraft) which is specific to diathermy in contrast to the irritating action of the other electrical modalities. De Kraft states that fibrillary contractions of muscle fibres in the very early state of peripheral paralysis can be arrested. Spastic conditions of the stomach, intestines, gallbladder can be promptly relieved. Even in apparently hopeless conditions as sclerosis multiplex, there are authentic reports in both foreign and American literature as to the beneficial action of diathermy.

4. The bactericidal action. There is evidence both experimental and clinical that the virulence of bacteriæ, especially of gonococci and pneumococci, in living tissues are markedly diminished after diathermy. Adding to this the unquestionable raising of the local resistance through hyperemia, the brilliant results of Cumberbatch in all forms of gonococcel infection are explained.

MONOPOLAR APPLICATIONS

If the voltage or tension of the high frequency current is further stepped up by an extra solenoid, and this current is tapped off on the special Oudin terminal of the diathermy machine, vacuum or non-vacuum (condenser) glass electrodes will be activated. From the distal surface of the glass, electrical charges are induced which can be applied to any part of the body monopolarly (the indifferent electrode in this case being the ground). Real surface heat is developed especially under the metal lined condenser type of electrode, and this can be utilized by treating mucous surfaces. Application with these electrodes can also be made more penetrating if used bipolarly; the active electrode is connected to one diathermy terminal and an indifferent electrode is passed against the opposite surface of the body and connected to the other diathermy terminal. Sinus affections, intranasal conditions can be thus treated efficiently. Monopolar high frequency applications can be used with benefit in superficial neuralgias, mild forms of neuritis, subacute forms of polyarthritis.

In drug stores and hardware stores, a cheap alternating current apparatus is being sold the country over under the name of violet ray machines. This current will light up glass electrodes, naturally their violet color has nothing to do with ultraviolet rays and all their therapeutic action amounts to is a mild skin irritation and gentle massage, as any ordinary liniment would do.

SURGICAL DIATHERMY

The employment of diathermy as a destructive agent has a very wide field. The aim of surgical diathermy is to produce a varying amount of electrical heat either for the drying up (dehydration) or carbonization (fulguration) or complete termoelectric coagulation of the tissues. This latter method should not be confounded with tissue destruction by the actual cautery, because in diathermic destruction the tissues are not burnt, but are coagulated and on account of the firm plugging of bloodvessels there is an absence of hemorrhage at the operation and danger of a subsequent secondary hemorrhage. With experience the depth of the coagulation can be regulated by the volume of current used and the length of the application.

Dehydration is accomplished by the monopolar application of the mild amount of high frequency current through a steel needle into the tissues with the effect that the tissue fluids slowly evaporate and the area treated converts into a dry mass. This is an ideal method for the treatment of superficial and benign blemishes of the skin and mucous membranes, as warts, naevi, moles, leucoplakias, and other conditions, with perfect cosmetic result.

Fulguration is the sparking of the tissues by monopolar application, causing a superficial cauterization from without in contrast to the dehydration from within in the former method. This cauterization, however, prevents the deeper penetration of the Oudin current and necessitates the curettage of the carbonized tissue if a deeper heat effect is desired. Some forms of benign growths may be treated by this method which was so enthusiastically proposed by de Keating-Hart fifteen years ago.

Finally electrocoagulation is the method whereby a heavy bipolar current is employed and a very penetrating and immediately destructive current is employed. An active electrode with a needle point or a flat disk is placed against the tissue to be coagulated and an inactive electrode is placed somewhere on the body insuring a direct line of current. The heat produced comes from within and with sufficient experience can be made to act to great depths. Malignant growths at any location, when accessible and not involving vital structures, can be attacked successfully by this method and its range application offers a still widening field in replacing cutting operations. The main advantages for applying high frequency currents for the destruction of malignancy, according to Plank, are: 1. The operation is bloodless. 2. Much less time is required. 3. There is very little shock. 4. There is a minimum of trauma. 5. The danger of metastasis is reduced to a minimum. 6. Postoperatively there is very little pain, reaction edema or toxemia. 7. Resulting scars are soft and pliable. 8. There is perfect control to an area as small as a needlepoint. 9. Results are better than with cutting operations.

The technic of the various methods of diathermy can be learned only by actual work under an experienced teacher. After having acquired sufficient working knowledge of the same, the only limit to the successful application of diathermy is the resourcefulness of the operator and his conception of the pathological condition in the individual case.

223 East Sixty-eighth Street.

The Treatment of Birthmarks by Physical Agents

JOSEPH JORDAN ELLER, M.D.

New York

Physiotherapy in some form plays the greatest rôle at present in the treatment and eradication of birthmarks. The older methods of therapy, such as excision, vaccination at the site of the nevus, injections of boiling water, the application of nitric acid and the treatment by hot air, have been replaced by methods which are more under control of the therapeutist and which uniformly give much better results than the older methods. Today, the following physiotherapeutic measures are used, namely, electrolysis, trichloracetic acid applications, x rays, radium, carbon dioxide snow, Kromayer light, and surgical endothermy (electrodesiccation and electrocoagulation).

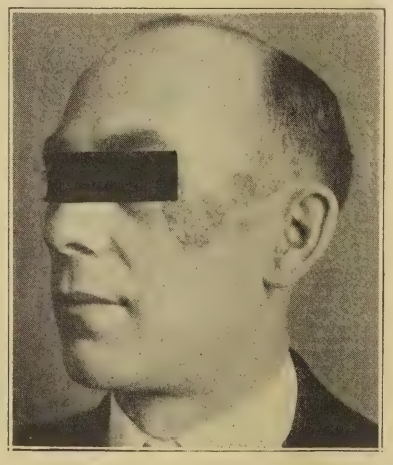

Fig. 1.—Port wine mark before combined Kromayer light treatment and carbon dioxide snow.

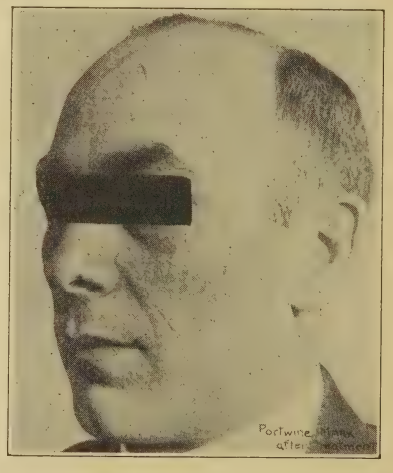

Fig. 2.—Port wine mark after combined treatment with the Kromayer light followed by carbon dioxide snow.

PIGMENTED NEVI

Brown pigmented nevus without hair.—This type of lesion varies in size from a pinhead to a quarter or larger. It is usually slightly raised above the level of the skin. Carbon dioxide snow gives the best cosmetic results for the larger marks and the application of trichloracetic acid at proper intervals is the method of choice for the small moles. Electrodesiccation is used for the removal of hairless brown nevi but with this agent there is apt to be more scarring than with either of the previous two.

Brown pigmented nevus with hair.—The hairs must first be removed by means of electrolysis. At this point I wish to warn against the removal of the hairs by means of x rays. This method has been used in some of the clinics, following which epilation, the pigmented mole was treated with snow, acid applications or endothermy, and bad scarring resulted and often with a return of the hairs. Quite frequently after the removal of the hairs by electrolysis the lesion disappears without further treatment. Should any of the pigment remain it is readily removed with applications of carbon dioxide snow or trichloracetic acid. Electrodesiccation is not used for the reason given above. X ray or radium irradiation is contraindicated and, in my experience, does not act well on pigment.

Black pigmented mole without hair.—This lesion is usually bluish black, having no hair and often shiny. It invariably is a dormant melanotic cancer and should be treated as such. If it is in an area not subject to irritation and it does not show any sign of growth, no treatment is advised. On the other hand, should there be an indication for removal, only the most radical treatment should be undertaken. Any conservative treatment will result in a general metastasis

and death within a short time. The best results are obtained by removing the lesion without disturbing or touching it. This can best be done by the use of the endotherm knife circling wide for at least half an inch outward from the lesion, or even an inch if the lesion shows signs of growth, and then cutting down for a half inch or more underneath, removing this whole mass of tissue with the mole intact. A day later radium heavily filtered is applied to the treated site as well as to the glands which drain the affected area. I have a few cases under observation which had been treated by the latter method described above and which were proved to be true melanotic moles and which have shown no sign of recurrence after two years. Despite the fact that the cosmetic result was disregarded the healthy tissue granulated so as to leave a soft smooth scar. The final outcome of these latter cases of course is not known and they will be kept under close observation. In all the other cases which I have observed and which were treated in a conservative manner, whether the lesions were growing or not, the patients died during the period of six to twelve weeks after treatment from a generalized carcinomatosis. A combination of the endotherm knife with radium and x rays gives better results than using any one of these agents alone. The endotherm knife seals the lymphatics and capillaries as it cuts and thereby lessens the chance of metastasis, while the opposite is the case with the ordinary surgical removal.

NEVUS VERRUCOSUS

This is a warty birthmark and is difficult to remove permanently. In order to do this a deep application of electrocoagulation is applied, following which the treated mass is removed with a sharp curette. X rays and radium must be given in such large doses for a permanent cure that they are both contraindicated. Carbon dioxide snow gives good results where the warts are soft and not deeply imbedded. It is always impossible to cure this nevus without more or less severe scarring by any method.

NEVUS FLAMMEUS (PORT WINE MARK)

Port wine marks are usually situated on the face and vary in size and color. They may be the size of a pea or may occupy the entire side of the face, or more. They may be pale red in color and blanch easily under diascopic pressure, or they may be dark red or bluish red and remain this color under pressure. They are never elevated above the surface of the skin. X rays and radium are absolutely contraindicated in the treatment of this condition. In order to cause their removal with this type of irradiation, whether with filters or not, unsightly scarring is always the result with more or less atrophy, keratoses, and pigmentation, and later the growth of epitheliomas.

Epitheliomas following x ray or radium burns are always of the metastatic type. Wickham and Degrais, Pusey, Mackee, and others have reported very poor results in the treatment of port wine marks with x rays and radium and advise strongly against this method of therapy.

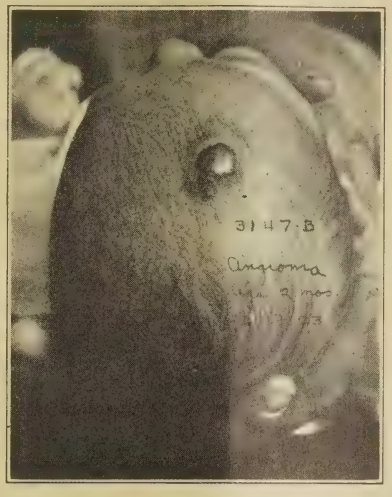

FIG. 3.—Angioma cavernosum before radium therapy.

FIG. 5.—Angioma cavernosum before radium therapy.

FIG. 4.—Angioma cavernosum cured by radium therapy.

FIG. 6.—Angioma cavernosum after radium therapy. Note return of hair on former site of nevus.

There have been demonstrations of cures by means of the use of the Kromayer light with pressure. I have used this method very carefully in twenty cases and have cured one patient, a young woman aged twenty-two years, who had a mark on the right temple about three inches in diameter which lightened under diascopic pressure showing it to be superficial. It took about a year to cause a disappearance and no scar remained.

A second port wine mark which was cured with

a good cosmetic result was on the face of a young man. The Kromayer light was used with some improvement. Later the mark was completely removed by carbon dioxide snow. In three other cases there was a slight lightening of the lesions by Kromayer light. All the others were a complete failure even though I permitted the light to be applied with great pressure under full current and for forty-five minutes to an hour at a time and causing blistering and tremendous reactions. These cases are now being treated with carbon dioxide snow and although there is slight scarring, the results are gratifying and very much better than the Kromayer light.

Fig. 7.—Nevus flammeus, before treatment with carbon dioxide snow.

There is now a much improved method of applying snow. Dr. Lortat-Jacob demonstrated his method to me at the St. Louis Hospital in Paris. By an ingenious invention of his, the snow is collected in a copper chamber which chamber is directly applied to the lesions. Only the metal comes in contact with the skin, and the pressure is accurately controlled by a spring gauge. The copper applicators are made into various sizes and shapes to fit the various lesions. The snow can be collected with this device in a few seconds. I have been using this method of carbon dioxide treatment and have found it to be much superior to the old method of applying carbon dioxide snow directly. Lortat-Jacob's apparatus is a good one for port wine marks particularly and he has shown several cases cured with only very slight scarring.

STELLARY NEVUS

Electrolysis gives the best results in these cases. As a rule one treatment to the centre of the lesion, using two to three milliamperes of current and leaving the needle inserted until this area becomes blanched, will suffice to cure this condition. There is no doubt that radium in the proper doses will cure these conditions but it seems that it is better to use a simple, harmless method, such as electrolysis. The technic is fool proof and no scarring will result if used in the above manner.

ANGIOMA CAVERNOSUM

In this type of bloodvessel birthmarks, the deep vessels, especially the veins, are involved. The lesions consist of soft tumors which vary in size from a pea to a walnut and larger. The tumors may be elevated well above the surface of the skin or the elevation may be only slight. The overlying skin may be normal. They often occur on the tongue, lips, mucous surfaces of the cheeks, etc. These nevi are more common in children, the explanation for which is that such lesions often undergo a slow spontaneous involution or are cured as a result of accidental traumatism. When cured in this manner, unsightly scarring may occur, so that I advise treatment in all such cases in order to avoid this. There are various methods of treating cavernous angiomas such as: radium, carbon dioxide snow, bipolar endothermy, x rays and general surgery.

Radium is the treatment *par excellence* and gives by far the best cosmetic results. In most cases with the proper technic, no scar will remain. Occasionally in a particular obstinate lesion one may get slight wrinkling. Full strength flat applicators are suitable as a rule, using filters of two millimetres of brass, thereby cutting out all the beta rays for the deep seated angiomas, while for the more superficial type, filters of one to two millimetres of aluminum are used. The dose should be just a little less than the amount required for a first degree reaction and it may be repeated every four to six weeks. The number of treatments required will vary with the size and depth of the lesion. Radium emanation tubes may often be used (with the proper filters) to great advantage on convex surfaces such as the gum, tongue, and lips. It can be put into dental molds and made to fit the lesion exactly. Radium gives such good results and is so superior to other methods of treatment for this condition that I feel any other form of therapy is contraindicated. However, the second choice of treatment is carbon dioxide snow given with sufficient pressure and at the proper intervals. It may, however, even with the best technic leave slight scarring. The third choice of therapy is bipolar endothermy.

Fig. 8.—Nevus flammeus, after therapy with carbon dioxide snow.

NEVUS VASCULOSUS (STRAWBERRY MARK)

In this type of angioma the lesion is erythematous and is elevated slightly above the surface of the skin. The lesions involve only the superficial vessels and vary in size from a pinhead to four or five inches. They are soft in consistency and may enlarge rapidly in a few years or may undergo involution spontaneously. Radium is by far the treatment of choice in this condition using filters of one to two millimetres of aluminum.

Due to the great increase in the number of physical agents in the armamentarium of the dermatologist and to the improvement in the technic of their usage in the treatment of birthmarks, much more satisfactory cosmetic results are now obtained in the removal of nevi.

Historical Medicine

A New View of the Boyhood of the Rev. Dr. Muhlenberg*

ROBERT ABBE, M.D.
New York

Dr. Abbe said that some years ago when crossing the continent, he studied the local papers of the cities en route and found in the *Omaha Bee* a novel column of advertisement called Swapper's Column.

A poor mother loses her babe and needs a sewing machine: She offers to swap her baby carriage.

A man has a good dog, he offers to swap with some one who has a canary which his wife wants.

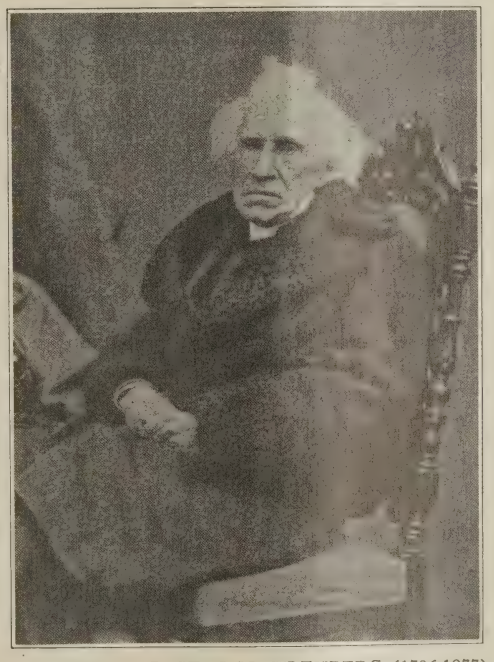
A surgeon offered his instruments and books, as he says, "for a shotgun, or something I can use."

So, since I have ceased using the scalpel, at our hospital, I find other interesting things that I can use like the doctor's "shotgun."

The executor of his estate has sent me a package of thirty letters, yellow with age, neatly folded, and each marked by the hand of Prof. George B. Wood, of Philadelphia, with the date and name of his friend, William Augustus Muhlenberg. A hundred years old were these new found letters.

The two boys, Wood and Muhlenberg, were students together at the University of Pennsylvania. Neither one had a dearer or more intimate chum; a boy's intimacy began then, when boys open their hearts to each other, which lasted until death.

Wood became the distinguished professor of materia medica of the University of Pennsylvania, author of many writings, but above all, the author of the great *United States Dispensatory,* continually enlarged from its first edition in 1833 to its twentieth edition now universally used—a heavy volume resembling the latest New York City Directory.



WILLIAM AUGUSTUS MUHLENBERG (1796-1877)
As the House Staff of St. Luke's knew him from 1858-1877

Prof. George B. Wood, Jr., succeeded his father in editing the later editions. I have brought the first and last editions of this monumental work for you to see tonight.

Muhlenberg became the divinity student, curate, pastor of three churches—founder of the Church of the Holy Communion in this city and of St. Luke's Hospital.

The letters would be of little interest did they not reveal the struggling efforts of a representative man, of a type commanding our sympathy, respect, admiration and love—aiming to live a consistently useful life—a hopeful, fearless, consecrated, and I might almost say, lonely life, carry high a banner which he would place on some unseen rampart, revealed only as Time unfolded his career.

Most of the living alumni of St. Luke's never saw this saint, the Rev. Dr. Muhlenberg. It was my privilege to live three years with him in old St. Luke's, and these letters give me a new glimpse into his boyhood which will interest you as it has me.

Many of us are starting our careers. Some are ending them. Go back with me a century, and see if we can discover in these letters the factors in his early career which carried him to the high position he attained. We see him, as a boy, keeping a diary, as was the custom of the gentlemen of those days, and this he continued till his death.

How much interest always attaches to the prompt recording of the incidents of any day of one's life, and the thoughts called out by them! Rereading of them recalls a vast store of otherwise forgotten experiences, and forms a fine foundation for the resources of social conversation now, almost a lost art, in these days of newspapers.

These old letters are like a bit of his diary. They tell something of the news of the day. The first letter, for instance, was from the student Muhlenberg, in Philadelphia, in 1817, to student Wood, taking a vacation in New Jersey. Letters went by saddle and stage coach, in two or three days for ten pence or a shilling, paid in coin, for there were no postage stamps then. It tells of a rumor current in Philadelphia that "Napoleon had escaped from St. Helena in a hogshead—on an American vessel."

Imagine the long three or four weeks' delay before this rumor could be denied! Sailing vessels—were the only news carriers to Europe. Even as late as 1864, in our Civil War, the news of the decisive battle that ended the rebellion was so important, that the Inman Line dispatched a special steamer to carry the news quickly to England. There was no Atlantic Cable until 1866.

These young college boys were one day bitten with the journalistic furor, and partly to help pay expenses, invited the best Philadelphia families to subscribe to *their* newspaper. A printed invitation with alluring promises (and a subscription card to be

*Notes of address to St. Luke's Alumni, May, 1922.

called for later) was left, by hand, at the door of every self respecting householder. After a few days the youthful editors had two responses, and later, Muhlenberg writes Wood that "the Committee have but 175 subscriptions, that not a word has been written of any of the articles to appear in it," and he fears "it will never see the light"—which it never did.

Later, divinity student Muhlenberg writes to medical student Wood to prescribe for his disease, laziness, by return mail. Again, he bemoans his apparent lack of "evident sanctity" in the profession he is preparing to follow, but assures "Dear George" that he is "anything but a hypocrite." Like many a student, he makes a lengthy analysis of his own character—"alternately melancholy and exalted." He writes: "I would as often die as live, for the prospect of a blissful heaven."

Again, how like his old self, as I knew him at eighty years, excusing faults in others, and condemning himself, for writing of their "Classmate A. ——", whom he denounces, and then, "regrets sending such a dirty letter, to such a nice correspondent," and asking Wood to "burn it up." I've no doubt "Classmate A. ——" deserved the scathing criticism.

How human is a line to his chum Wood from Philadelphia in August, 1817, that it is "much too hot to study!"

His next letter is full of pathos. "How fortunate," he says, "that I came back to Philadelphia," for the next morning his grandmother expired. He writes: "Although we had been in long expectation of the event, and used to talk with calmness about it, *when it happened,* it affected us all greatly" . . . "I never before saw a person die," he writes. "It is truly an awful sight, even in one run down by sickness and old age. How much more melancholy it must be in blooming youth cut down in the midst of health."

His experiences with the Great Reaper, which his hospital function caused to accumulate in later life, now were initiated, as shown in this same fine letter. "I have just heard," he continues, "of the death of the Right Rev. Dr. Dehon, Bishop of South Carolina. He died suddenly of bilious fever. He was one of the most beautiful men I have ever seen. He was thought, when in Philadelphia four years ago, very much to resemble Henry Rawle. He had Henry's eye, and something of his features, but his complexion was much more florid. In the pulpit, in his episcopal robes, his appearance was something more than human. His voice was music to the ears, and his style of writing accommodated to his manner. The cadence of his sentences was melodious and full. The Church of South Carolina has lost one of the highest lights of the sanctuary, and the circle of society in which he moved an inestimable and brilliant member. He was a man of fervent piety and fine genius. He was not forty, when he died." "Forgive me, George, forgive me," he writes, "my feelings have led me into fields into which you have unwillingly followed me. The news of the Bishop's death, being so fresh upon my mind, together with my respect for his character, and admiration for his person, plead my apology."

I have made this extract from this letter to Wood because it brings to my mind an incident, more than half a century later, when with Dr. Muhlenberg in a room in the dear old hospital, I stood by the death bed of another beloved Bishop of the Church, Bishop Armitage, who died shortly after I entered as an intern.

It was the first death I had ever witnessed. Dr. Muhlenberg must have seen a thousand since his grandmother's death. My emotions were intense. My eyes were wet, as the last breath was drawn and the overwhelming silence followed. My impressionable young mind asked, "Where is the soul, released but now! Open the window, and let it out." The scene is as vivid as if it were but yesterday. Yet the venerable saint standing by my side, dry eyed, and without visible emotion, compressed his lips and, dressed as he always was in his long purple dressing gown and slippers, quietly shuffled out of the room, down the hospital corridor, to his room, where, I doubt not, he uttered a prayer, *alone.*

In August, 1818, we find him on a vacation, in Bethlehem, Pennsylvania, among that unique settlement of German refugees, already a century old, who continue even today their annual musical festival. He writes of these "remarkable religious and musical people, where all orchestral music was played in schools and churches by the people, who were like Quakers in their simplicity." Dr. Muhlenberg's love of fine church music, of chorals, of Bach, of Gregorian chants, must have been an innate appreciation.

A little later we find him preaching in Lancaster, his first parish. With characteristic humility and self analysis he writes his "dear friend": "My irresolution and want of method are prominent traits of my character." One often sees this inward suffering revealed when men are working toward some great goal. In this parish he "finds the town full of gossips," and says, "I have to be very circumspect myself." Then, in serious vein, he opens his heart to his friend—his first talk on the doctor's attitude to the church—and ends by promising him "another sermon."

Here begins an evident entering wedge that develops in the friendship of these two admiring souls. It is typical of life. Two equally noble spirits, each bearing a manner "Excelsior." Through the same rift in the clouds, one sees only the vision of the Heaven of religious thought; the other, the intellectual and scientific progress away from dogma; both equally moral and noble. The religious devotee, suffering inward torture of his soul, praying to bring his loved friend to see the light as he sees it.

Six months later, Dr. Muhlenberg writes a long and intimate letter expressing "the grave and serious task he is in for as rector." Then he expounds the Scripture, and gives his "Dear George" another dose of theology, coupled with that yearning love which would bring them both to think as Muhlenberg's conviction led him to think.

We have no record of Wood's answers to these letters, which were sacredly kept, folded and filed, with Muhlenberg's name and the date of reception. So orderly was it all, that it implies the deep respect Wood had for this young Pastor. I have little doubt that a kindly and tactful, but unconvinced, reply, was sent.

These letters, mellow with age, and running over thirty years, we may read with respectful analysis. There is evidently a widening breach in the warmth

of correspondence, and though Muhlenberg ceases to speak of religion, the letters become semiannual and less confidential. This abatement of ardor for converting his "Dear George" measures up to his later liberal toleration for indivdual thought, but he yields not one jot of his conviction of the full measure of Christian supremacy. If he suffered defeat in this cherished venture, while his heart ached, he vaunted no superior claim. He simply restrained himself. That attitude is a reserved privilege of all broad-minded clericals.

I recall one beautiful illustration of this sense of defeat which happened to Dr. Muhlenberg while I was house surgeon in 1876. One of the outstanding figures in the world was Charles Bradlaugh, the great agitator in English and Irish politics, a member of the House of Commons with Gladstone, and a thorn in the side of the British Government. He visited our country to spread broadcast his liberal views. He was taken ill at his hotel in New York and brought to St. Luke's Hospital, then on 54th street and Fifth Avenue, the site of the present University Club. The chill and high fever developed pneumonia. With characteristic bravado this powerful man refused to go into a private room, as he boasted he "had always shared hardship of barrack life with his people, and the ward was good enough for him." We put him in a ward. In two hours Bradlaugh had had enough of it, and as he bid fair to go out of his mind, I put him in a large room next to Dr. Muhlenberg. I found him full of interest and character and grew quite fond of him during the month he was under my care. Dr. Muhlenberg took the first opportunity during convalescence to visit him, as was his habit, and ventured a little missionary work, which was not resented but met with intelligent and forceful argument. After one or two visits Dr. Muhlenberg gave it up. The atheist was too strong for him. Dr. Muhlenberg never lost heart; he had fulfilled his duty and cleared his conscience.

About that time one of our brilliant surgeons, Dr. Tom Sabine, whom everyone knew as a son of the Reverend Dr. Sabine and a scholarly atheist, fell sick and died of tuberculosis. Everybody loved him. One of his father's sympathizing parishioners asked the father if he didn't feel dreadfully about his son's irreligion. "Oh, no!" he said, "the good Lord will take care of Tom." That was the attitude of Dr. Muhlenberg.

In January, 1822 (exactly a century ago) Muhlenberg, the young, lonely curate in Lancaster, writes, "Dear George, more than ever I need a friend to talk to. There are good women a plenty and I enjoy them, but *men* are few."

From that period of Dr. Muhlenberg's life we begin to see the development of his idea of the crying need of our country for education of the people by the state. In this letter he narrates his appeal to the Pennsylvania Legislature to extend educational methods to public schools for the poor. It is not easy for us, today, to realize that a century ago State education was almost unknown. Our public school system is one of the monumental growths of our unique democratic civilization. We see Dr. Muhlenberg's one unalloyed principle of life was service to the brotherhood of man.

In the next letter, three months later, "Dear George" gets a homily on human weakness, phrenology, and "Cracked brains." And, following this, a copy of *Butler's Analogy* for him to read, hoping it will "soak in"; then, a little more preaching, trying to nail it. It evidently had little effect. "Dear George" has been more interested in social pleasures and, at the same time, announces his marriage engagement. This surprise sweeps Dr. Muhlenberg off his feet, and he writes Dr. Wood, asking, in a most naive way, "How, now, do you view your other female friends?" He says, "Your eye no longer wanders." Many apologies he gives for not warmly congratulating Wood, "as he does not know the lady." How Wood received this awkward compliment we do not know, but, the engagement being made public, Dr. Muhlenberg writes a dear letter "claiming the honor of tying the indissoluble knot by virtue of ancient contract." "Hymen," he writes, "is to complete what the little blind boy has so successfully begun."

We can imagine the solitude in which Dr. Muhlenberg was steeped after this. There was no *estrangement*, only the *contrast*.

His next letter, three months later, is full of sadness. We can read between the lines. He writes regretting "he cannot come to the wedding," and continues, "The bright prospects of my friend, I contemplate with heartfelt pleasure, from amidst the dark and melancholy gloom with which my own are shrouded." How dramatic that moment in his isolated but beautiful self abnegation! A line from Hamlet could not speak more strongly.

Three years intervene ere the next letter. Muhlenberg tries to be cheerful and gossip about his people, but lapses sadly, and recommends Wood to "read" *Dwight's Theology* "every Sunday."

Two months later, he probably had had an answer, as he writes "regretting the tone of his previous letter" and evidently tries to be more cordial.

Four weeks later his letter is long and full of news but entirely in poetic form, which can only be explained as a salve and comfort to his own soul, and giving a restorative lift to old friendship, which had been cast down of late.

Seven years now elapse during which, if any letters were written, Wood did not keep them.

Then Muhlenberg writes two letters without the affectionate touch of old, and taking occasion to note the public announcement of "the gift of the enormous sum of $2,000,000 to found Girard College to the exclusion of any theology." This stirs our dear pastor to call it "an Unchristian Act."

Three years now elapse and Muhlenberg is settled in a new parish at Flushing, where he feels joy at expecting a visit from Wood.

Another year passes and Dr. Muhlenberg and his brother, F. A. Muhlenberg, write to ask Wood, then professor at the University, to recommend "a fine physician to fill an expected vacancy among the Flushing doctors, to be also professor of chemistry, minerals, and practice of medicine, and to expect an income of $2,500 professionally, and $500 salary, charging something for the good will of the man getting out." This was the first step in founding the Flushing Institute, the future St. Paul's College, the first church college for education for the Ministry.

After another long interval Muhlenberg writes Wood that he hopes, "if ever I become a great man, no one will publish my letters, as thereby, anyone would discover procrastination is my besetting sin." He writes, "As Cicero had, for his speeches, a common introduction, so I have, for my letters, an apology for not writing sooner."

The last three letters in 1838 pertain to Muhlenberg's great scheme to establish St. Paul's College, the first church college in this country, and to get money for it, by loans and gifts.

* * * *

How like a stage scene the curtain rises on this first act—the boyhood life of a heroic figure, whose later career as an educator, humanitarian, and founder of St. Luke's Hospital is well known.

The affection of these two souls never cooled or died out. A year before Muhlenberg's death, Wood, also an old man over eighty, visited him.

Muhlenberg writes in his diary, "Wood was the best scholar of his class." Again he writes, "How much better and wiser I have grown." Again, "God alone knows how I agonize, in prayer, to be useful."

Some of his aphorisms, born of experience, are as good as Franklin's trite sayings. He writes, "Never, if you can help it, tell bad news, at night."

All these letters antedate by a dozen years his settling in New York, and laboring to found our hospital in 1852.

It has been delightful to me, to get this glimpse into an early period of a life which, by the inevitable law of evolution, eventuated in the masterly character of William Augustus Muhlenberg.

He made a marked impression on the growth of the great Episcopal Church in our country.

He was not only the founder of our beloved Hospital but—as Bishop Lawrence of Massachusetts wrote me a few days ago "was one of the few real prophets of our church in the first century—indeed—a unique prophet—and when we have not followed him we have gone wrong."

These introspective letters of boyhood, read in the light of his subsequent life, show that he was neither "lazy," "procrastinating" nor "melancholy" but always in a mood of spiritual exaltation.

40 West Fifty-ninth Street.

Leonardo Da Vinci, Anatomist and Physiologist

LEOPOLD VACCARO, M.D.
Philadelphia, Pa.

(*Concluded from page* 569)

The Madonna sits in the midst of a great classical ruin; and in the intense dramatic action of the worshippers and the crowds endeavoring to approach, the author has surpassed the highest achievements in the Early Renaissance. Of the other works ascribed to this youthful period none seems genuine except St. Jerome (Vatican), a fine anatomical study. The small Madonna del Fiore in the hermitage St. Petersburg, is after Leonardo's design, but Berenson attributes to him an unfinished profile of a girl, in possession of Donna Laura Mingnetti at Rome.

Leonardo first visited Milan about 1482-83, as the bearer of a present from Lorenzo dei Medici, to Lodo vico il Moro, the reigning Duke. His present was a strange musical instrument sounding like a lute, and invented by Leonardo himself, who thus sang his way into the Duke's favor. Among the artist's papers is the brief of a curious letter which he wrote to the Duke after his return to Florence, stating his various accomplishments. None of the ten divisions of his letter are devoted to his abilities as a military and civil engineer; and in the last he states his prowess in architecture and in sculpture. "In painting also, I can do what may be done, as well as any other, be he who he may." The earliest documentary evidence of Leonardo's presence in Milan dates from April 25, 1483, and he remained there until his patron was driven from the city by the French in 1499. This was the most fruitful period of Leonardo's activity.

His work in Milan was important and varied, as a sort of general factotum for the ruler; he was principal engineer in his numerous military enterprises, constructed the Martesana Canal, and directed great festivities, as when Lodovico married his niece to Emperor Maximilian. He was also active as architect, being one of those employed upon the Cathedral of Milan, and he probably designed other public buildings. He found time to prosecute his studies in anatomy especially in animals, with Marco della Torre, and to assist Luca Pacioli in one of his mathematical works. At the same time he was at the head of a large band of pupils; whether or not they constituted the supposed Milanese Academy for them, he wrote the *Treatise on Painting;* and it is certain he designed paintings which they carried out. The artistic task in which Leonardo took chief interest and indeed the dearest plan of his life, was the colossal bronze monument to Francesco Sforza, the father of Lodovico. On it he labored constantly till his departure from Milan in 1499, without having brought it to completion. His interest is attested by the numerous studies of horses, in all manners of positions, in sketches for the monument and reliefs in wax and clay. The model for the horse, twenty-six and a half feet high, was completed when the French occupied Milan in 1500, and formed a target for the Gascon archers. Had Leonardo completed this monument it probably would have ranked as the greatest equestrian statue of the Renaissance, surpassing Verrocchio's Colleone as far as the latter did Donatello's Gattemelata.

Of his paintings during the early Milan period the most important panel is the known Virgin of the Grotto in the Louvre, executed for the Confraternita

della Concerione (1482-90). In this Leonardo has finally solved the problem of chiaroscuro in the striking contrast of the faces of the Virgin and the two children in the darkness of the grotto. From 1494 to 1497 Leonardo labored on his masterpiece, The Last Supper, a wall decoration in the refectory of the Monastery of Santa Maria delle Grarie Milan. Because of his use of tempera colors directly upon the wall, a surface unfit for the purpose, and because of neglect and vandalism of monks and soldiers the grand original was reduced to a ruin.

All of the other pictures painted by Leonardo during this period has been lost.

In December, 1499, after the expulsion of Duke Lodovico, Leonardo left Milan for Venice. To a brief sojourn at Mantua we owe two beautiful drawings of Isabella d'Este (Louvre and Uffizzi) though he never painted for her the desired portrait. He remained at Venice till about 1500, when he retired to Florence and assiduously devoted himself to the study of mathematics.

In 1502 Leonardo entered the service of Cesare Borgia as a military engineer rendering important services in the different parts of Central Italy.

When the French temporarily abandoned Milan in 1513 Leonardo paid a visit to Rome. In 1516 he returned to Milan. He was made court painter at a salary of 700 gold scudi annually, besides being confirmed in his previous possessions. By order of Francis I he bought up all his own pictures that could be had whence the collection of the Louvre, and the same year he accompanied the King to France. He passed the remainder of his days in the residence assigned him in Castle Claux, devoted to scientific research and died there soon after the date of his testament, May 2, 1519. He died in the presence of his friend, Melzi, who had been his constant companion the latter part of his life, and to whom he left his invaluable manuscripts and his various instruments.

Leonardo was the most extraordinarily versatile genius of that age of geniuses, The Renaissance. As a man of science, he towered above all his contemporaries, and had his views been known and generally published, they must have revolutionized the science of his day. That they were not known is perhaps due to the fact that his manuscripts were almost undecipherable, being written with the left hand, backhanded and from right to left. With an almost inspired glance he divided the secrets of Nature, making discoveries which it has been reserved for our own time to perfect. A consummate master of anatomy, he even divided the circulation of the blood and the action of the eye in vision. He made astounding observations in meteorology. Knew the earth's annual motion and the effect of the moon upon the tides; foreshadowed the hypotheses of the elevation of continents, and discovered the nature of fossil shells. He originated the science of hydraulics, and probably invented the hydrometer; his schemes for the canalization of rivers is still of practical value. He invented a large number of labor saving machines, very remarkable for his day, and as a mathematician he takes high rank especially for his study of spirals.

In the art of painting he wielded the greatest influence. He was the pioneer of the High Renaissance, the first to achieve that complete mastery of form and technic which admitted of a new freedom of handling a new truth to Nature and life. He was the first to attain a sound and complete mastery of anatomy and to introduce color in the highest sense, into Florentine paintings. By the use of sfumato a smoky, hazy quality—he achieved a remarkable melting tone and blending of color, he was the first great master of light and shade, which he made witching and lovely. His drawings reveal the consummate draftsman seeking rather after finesse than general effect. They may be found in that principal European collection, especially at Windsor. Among the principal are the studies of his principal paintings such as the *Kneeling Leda* (Chatswortly and Ducat Palace, Weimar), *Neptune Driving His Team, The Battle of the Standard, The Last Tuffe,* the magnificent head of Leonardo in old age (Royal Library, Torino) and the large series of caricatures in which he displays a remarkable sense of humor. Especially characteristic of Leonardo's art are his landscape backgrounds, into which he was among the first to introduce atmosphere and perspective, that mysterious quality which heightens most admirably the effect of the picture and the subtle mysterious smile which Vasari has characterized as more than human. The influence which he wielded over Italian art was profound and sound. The chief masters of the High Renaissance in Florence—like Raphael—Andrea del Parto and Bartolomeo—all learned from him and transformed the School of Milan.

This peerless painter, sculptor, architect, engineer, mathematician, astronomer, meteorologist, musician, poet, inventor and philosopher was simultaneously a preeminent master anatomist and physiologist "the most richly gifted among all the sons of men" from that rich land of geniuses: Italy.

Bismuth Poisoning Following Oral Administration of Bismuth Subnitrate.—William H. Resnik (*Bulletin of the Johns Hopkins Hospital,* May, 1926) reports a case of bismuth poisoning in a colored woman of thirty-five years following administration of bismuth subnitrate by mouth. The important symptoms described were a bluish-black discoloration of the gums, tongue, and buccal mucosa, with slight ulceration, moderate anemia, basophilic stippling of the red blood cells, with tenderness and swelling of the parotid glands. There were also abdominal colic and evidences of a mild peripheral neuritis, but the dependence of these symptoms on bismuth poisoning is questionable. The general picture resembled very closely that due to lead poisoning. The patient recovered.

SUPERSTITIOUS SURVIVALS IN SURGERY

Science moves, but slowly, slowly, and with many halts where are entrenched superstition, magic, ignorance and emotional repressions. We have progressed a bit beyond the days when a drug was supposed to produce good red blood because itself was red or to act on the uterus because its shape resembled that organ, but we still see survivals of mysticism in medicine and even in its supposedly scientific sister, surgery. The difference is that now we bolster up our magic by statistics.

In the realm of antisepsis, one would suppose, we would find no room for the emotional element. Surely here it is a question of finding those agents which destroy germ life and are comparatively innocuous to living tissues. But this is only partly true.

About a score of years ago everyone worshipped at the shrine of the great god, iodine. Every cut was soused with iodine, chests were painted with it for pleurisy, painful joints were bathed in it, and surgeons recommended painting the hands and arms with it before operating as a complete precaution, obviating other antiseptics and rubber gloves. Emergency hospitals used gallons of it daily and many interns were solemnly taught that if they applied iodine to every wound they would never have an infection. Well, iodine was and is a useful drug, but surely not as omnipotent as was held in some quarters. In fact, the suspicion gradually took form that its popularity was due, in part at least, to its pungent smell and striking color.

And now a new antiseptic idol has arisen: mercurochrome. Walking through the wards nowadays one gets the impression of a Turner sunset. Everywhere are splotches of vermilion. Here a sprain, there a laceration and in the other place an eruption, all are daubed with scarlet. The psychic effect is no doubt good. The intern feels that he has done something effective and the patient is impressed with the sanguinary effect. Now if one could only be sure that the average microbe has a well developed artistic sense and is not suffering from daltonism. On the other hand, we cannot be sure but that these miserable organisms are so lost to all chromatic sensibilities as to be entirely indifferent to anything but their own sadistic desires.

Iodine and mercurochrome do not exhaust the list, by any means, although they have had the largest number of worshippers. There have been other brightly colored antiseptics which have made their transient bids for the surgeon's favor as Harding blue did yesterday for that of his wife and Chanel red today. Picric acid had its followers for a while, but perhaps the unconscious associations with yellow were such that its vogue was fleeting. For a while also methylene blue had its admirers, but one hesitates to say that this drug reminded any scientist of youthful indiscretions. At any rate, it was dropped. And then for a while the passionate purple of potassium permanganate was the thing. Enthusiasts recommended its use in all strengths from one to ten thousand to the pure crystals. It too passed on.

And now in some quarters the suspicion is gaining ground that there is no antiseptic which is magic in its effects, that pungent aromas and brilliant hues have but little to do with therapy. Among the more scientific surgeons there has grown up a sort of indifference, as it were, to color schemes, a conviction that rigid asepsis is the thing after all, and that when a possibly infected wound is treated with any antiseptic whatever, there is no guarantee that sterilization is complete.

And so step by step we are emerging from the romantic past of medicine into the practical present. We lose perhaps some color in so doing, but then we can always escape from a too drab reality via the neighborhood movie.

THE TREND OF MEDICAL PRACTICE

That the mode of medical practice is changing is so obvious that all are agreed on the point. In former editorials attention has been called to the fact that concentration on specialism and group practice has altered already and is altering the methods of medical practice hitherto in vogue in this country. At last year's meeting of the American College of Surgeons at Philadelphia, the address of the president, Dr. Matas, presented the situation clearly from this point of view. His address was dealt with editorially in this journal.

At the meeting of the British Medical Association at Nottingham the presidential address by Mr. R. G. Hogarth discussed another aspect of the changing conditions of medical practice, that of preventive medicine, which seems as if it would be the medicine of the future in Great Britain. He urged that the efforts to promote good health and to increase the span of life should be directed to the raising of the standard of fitness throughout the whole community. And the statement no doubt means that by the scientific practice of preventive measures, personal and domestic hygiene, good housing and so on, the chronic diseases which are the bane of modern civili-

zation shall be either nipped in the bud or by judicious treatment robbed of much of their power for evil. Allowing that preventive medicine will be largely the practice of the future, then by what agencies shall this form of practice be most efficaciously conducted both for the benefit of the community and of the doctor?

Mr. Hogarth sketches the possible or probable future of medical practice as the exposition of a benevolent state socialism in which, of course, the doctors play the parts of educators of the public in the leading principles of preventive medicine and who also are chiefly responsible for the proper application of these principles. He holds that if preventive medicine is to have full sway, it must be one of the paramount duties of the State to concern itself more and more intimately with the health of the nation. He truly avers that while the science of medicine used to be mainly empirical and the causes of disease were either unknown or wrongly attributed, preventive measures by the State were little thought of.

But in Great Britain changes have taken and are taking place in this direction with regularity. One straw which shows plainly which way the wind is blowing is the long series of public health acts and the creation of the Ministry of Health; these happenings, as Mr. Hogarth says, "attest the full recognition and acceptance by the State of this essential administrative function." Moreover, he adds that in Great Britain the right of the State and of the public authority to invade this particular domain is no longer challenged. We are now accustomed to the need for efficient drainage for a pure water supply and for a reasonably pure milk supply. By the scientifically intelligent application of such measures big epidemics, with the exception of influenza, are in civilized countries occurrences of the past. And it now remains to grapple with the chronic and certain of the acute diseases by as vigorous an application of the principles of personal and domestic hygiene, industrial hygiene and healthy environment generally as the application of public health measures have been applied. Also it may be predicted with as great hope of success. As Mr. Hogarth states, knowledge of what to do is fairly complete; the practical difficulties are connected with administration, how to deal with the borderline cases, and how to make the best use of the money at disposal, for improvements are always costly and public expenditure can only be met either out of rates or taxes. Public opinion has to be educated continuously all the time and, as said before, the chief part of this educative campaign falls within the province of the doctor.

The scope of preventive legislation is almost limitless. This remark applies to all countries, but Mr. Hogarth goes on to say that we are likely to see the State interfering, or intervening, more and more in the interests of public health. This last remark applies to Great Britain.

However, although Mr. Hogarth admits that the tenets of personal and domestic and industrial hygiene, etc., are the foundations of preventive medicine, and while he is prepared to allow that in order to carry them out to the best advantage the aid of the State must be invoked, he appears to view the entrance of the State into the field of preventive medicine with some degree of distrust and misgiving. He rather seems to be in the position of one who agrees with the general principles of State control of preventive measures because he is aware that they cannot be effectually used to the greatest advantage without the aid of the State, yet he is somewhat dubious as to the outcome. And this attitude represents, perhaps, the sentiments of the majority of the British medical profession. For instance, Mr. Hogarth refers thus to the Ministry of Health: "But now that the idol of State socialism has been set up for our worship, we may be sure that sooner or later the theorists will attempt to invest the Ministry of Health with increasingly autocratic powers, and will seek to transform the whole medical service of this country into a State service, with State hospitals, State examinations for degrees, and the State payment of doctors." In short, the handing over to the Ministry of Health of autocratic powers may be, and this is the fear, the insertion of rather more than "the thin end of the wedge" leading to State control all round, and may result in the splitting of the solid structure which has been built by individualism. It appears to be feared that State control of questions relating to health will destroy to a large extent the independence of the medical practitioner. Not longer will he be an individualist, but dominated by the State as represented by the Ministry of Health. Of course, Mr. Hogarth is right when he says that this would be a perfectly logical development in a socialist State, nor can it be pretended that such a system could not be worked. But whether it would be as efficient as the present British system, whether it would be as acceptable to the general body of the people, and whether the vastly increased cost would be repaid by equivalent advancement of medical knowledge or improvement in the public health, there is room for the gravest doubt.

At any rate, the situation in Great Britain seems to be that the character of medical practice is changing in the direction of preventive treatment rather than of carrying on the traditional methods of creative and remedial treatment, and it is thought that preventive measures cannot be pursued successfully without the aid of the State. The course of events in Great Britain from the viewpoints of the public

and the medical profession will be watched no doubt with much interest and some anxiety by their brethren in this country.

NORTH CAROLINA WARS ON MEDICAL FAKIRS

An interesting account of the successful "showing up" of what appears to be one of the most harmful of recent medical fake practitioners is published in an editorial in a late issue of *Southern Medicine and Surgery*. The writer tells us that, after careful study and observation of the evil influence of medical charlatans on public health work and consequently taxation, on human suffering, and on the efforts of the medical profession as a whole, he determined "to exert himself to make North Carolina an uncomfortable place for those who come in to tamper with the health and tap the pockets of her people, to the point of making them wish they hadn't come, and of causing them to tell the news to their motley brotherhood and sisterhood, so that all of this ilk would check North Carolina off their lists of boob states."

His first opportunity came almost immediately, when he read in a Charlotte paper that "North Carolina's healthtorium, of which Dr. Stevenson is the founder, is the realization of a twenty year ambition. It is a place for people with tired nerves or bodies who are seeking rest and *rejuvenation,* according to Dr. Stevenson. Here the *patient* may 'get back to natural foods, sunshine, outdoor living, and right thinking' the psychologist says." Not ever having heard of North Carolina's or any other "healthtorium," the writer secured an interview with its founder, "Dr. Stevenson," in which she described some of her marvellous cures, said that her institution had appointed a "consulting staff" from among the most prominent doctors of the state, that her brother was chief surgeon to the American Hospital in Paris, and that she herself was a graduate of the medical school of the University of Geneva. Soon afterwards a North Carolina Sunday paper printed a two column photograph, under which Arthur Brisbane, of the *New York American,* was quoted by the lady as having said, "God was kind when He gave to the world this radiant woman," and the further statement added: "An intimate friend of the late Sarah Bernhardt, a coworker with Pasteur, author, lecturer, and dietitian, Dr. Julie LaSalle Stevenson was called 'the Bluebird of Happiness' by Maeterlinck, the Belgian poet." Letters were sent to the chief surgeon of the American Hospital at Paris, to Arthur Brisbane, to the Medical School of the University of Paris, the *Institut Pasteur,* Maurice Maeterlinck, and the American Medical Association, citing the representations made by Dr. Julie LaSalle Stevenson. To all these inquiries came responses denying ever having heard of the lady in question, with the exception of that from the American Medical Association, which quoted data from its quackery records about a certain Julie LaSalle Stevens, who is probably the same person. It will be interesting to quote from this letter from the Bureau of Investigation of the American Medical Association: "So far as we have been able to learn, Julie LaSalle Stevens is not a physician—at least we do not find that she has ever attended any reputable medical school in this country or been licensed to practise medicine in any State in the Union." An outline follows of the data about her in the quackery records, consisting of quotations from various newspapers in Davenport, Iowa, Newark, Ohio, St. Petersburg, Florida, and an advertisement run by her in one of the "McFerrin's Health Bulletins" issued in 1925. This advertisement states that her "school for the well, where students will be taught how to guard against most diseases, is now open at 29 Fifth avenue, New York, in charge of Dr. Julie LaSalle Stevens, international authority in dietetics and nutrition for fifteen years." She asserts also that she is forming classes that will afford "dietetics courses of six lessons to physicians, nurses, teachers, business men, parents, housewives." The editorial in *Southern Medicine and Surgery* quotes in full all of the above mentioned letters and their replies.

The case was brought by the editor of the journal before a meeting of the Medical Society of the State of North Carolina, held the week after the papers carried the news of the new "healthtorium." Soon after this the Mecklenberg County Medical Society met and took action in the form of a detailed statement of facts and findings, concluded with the following resolution:

Resolved:

1. That we hold it an act prejudicial to the health of the people of the State for a newspaper to give space to claims of any one representing himself or herself as qualified to advise in matters of health, until testimonials have been carefully investigated, by direct communication when possible, and where this is impossible by calling the matter to the attention of the local medical society and hearing what evidence they may be able to present;

2. That we submit the case of "Dr. Julie LaSalle Stevenson" on the evidence adduced;

3. That we give the evidence and this action as wide publicity as is practicable; and

4. That in the interest of the physical and mental health of the people of North Carolina, we urge similar action on the part of all regular medical bodies when similar situations arise.

J. P. Kennedy, M.D.,
Secretary.

The writer concludes his editorial with the following statement, with the truth of which all of the medical profession will agree:

It is a sad commentary on a community that a smooth tongued stranger would dare come in, without credentials, represent herself as an intimate of many world renowned persons, and as having been graduated from three great universities; and a sadder one to recall that, apparently, these fraudulent representations were accepted as authentic until inquired into by doctors. Is there not need for protection? This fight is not on an individual, but on the whole system which this individual represents. . . . The desirable and desired object is to awaken doctors to the possibilities of resistance, and the intelligent portions of the general public to the duplicity and mendacity of this sample of the whole lot.

The North Carolina medical profession are to be congratulated on the definite stand taken and their quick action in this case of quackery which might have been a great danger to the health of the community if not immediately checked. Their example should be followed by other States of the Union which have not been so wise or active.

Obituary

ERNEST V. HUBBARD, M.D.

New York

Dr. Ernest V. Hubbard, who died at his residence in this city on October 24th, was born in Nashville, Tenn., in 1874. He took his medical degree at the College of Physicians and Surgeons in 1898. He was a surgeon on the staff of the Manhattan Eye, Ear and Throat Hospital, having specialized in laryngology. He was a member of the Society of Colonial Wars, the Sons of the American Revolution, the University Club, the American Laryngological, Rhinological, and Otological Society and the New York Academy of Medicine.

JOHN VAN DOREN YOUNG, M.D., F.A.C.S.

New York

Dr. John Van Doren Young, who died in New York October 25th, was born in Plainfield, New Jersey, October 3, 1864. He was the son of the late Mary J. Garrison and Dr. John Young. He came from a family of medical men, being the fourth in direct line.

Dr. Young received his early education in private and public schools and the Newburgh Academy. His medical degree was received from the College of Physicians and Surgeons, New York City, in 1888. He served as intern at St. Luke's Hospital and the New York Nursery and Childs Hospital, beginning private practice in 1890 in New York city, which he continued until his death.

Early in his career he devoted his energies to the study of gynecology and later became a specialist in this line, devoting much of his time to obstetrics also. The combining of these two specialties he deemed necessary to the mastering of either.

He was attending gynecologist to St. Elizabeth's Hospital, professor of clinical gynecology to the Polyclinic School and Hospital, consulting gynecologist to the Hackensack Hospital.

He was greatly interested in organization of medical men for their own protection and the advancement of the Profession. The Medical Society of the County of New York was his greatest interest, he having served this organization eighteen and a half years as its secretary. He was also secretary of the Physicians Mutual Aid Association for fourteen years.

He was a Fellow of the American College of Surgeons, the New York Academy of Medicine, the New York Obstetrical Society, a member of the County and State Societies and the American Medical Association, the Alumni Society of St. Luke's Hospital, the Medicosurgical Society, of which he was president in 1922.

He was a Mason, a member of Kane Lodge, of which he was Master in 1907; he was also a member of Jerusalem Chapter No. 8.

JOHN HOWARD MUMMERY, F.R.C.S., D.Sc.

London

One of the best known dental surgeons of the world, J. H. Mummery, and who was particularly well known in this country, died recently in London at the age of seventy-nine. Mr. Mummery was the son of a distinguished dentist whose researches into the causes of teeth decay are still authoritative. As a young man Mummery was renowned for his knowledge of dental microscopy, indeed his researches covered almost the whole range of dental anatomy and pathology. His papers dealing with the development of the teeth and the innervation of dentine are of especial importance. The investigation of this latter subject was most laborious, but eventually Mummery was able to prove that the dentine of the teeth is abundantly supplied with nerve fibres. Many of Mummery's conclusions have been accepted by dentists the world over, and he was one of that small band whose reputation was truly international. His vitality was remarkable and in some respects the last ten years of his life were the most fertile. He was seventy-two when he wrote a book on *The Microscopical and General Anatomy of the Teeth,* which became a classic almost at once.

He was a member of the Committee for the Investigation of Dental Disease of the British Medical Research Council and carried out some important work for that body. He was awarded the C.B.E. for his work on injuries of the jaw during the Great War. The University of Pennsylvania conferred on him the degree of D.Sc. He had been a president of both the British Dental Association and of the International Dental Federation. The English College of Surgeons made him an honorary member, a distinction seldom given and therefore a greater honor. Mummery was a man of great charm of manner and of unfailing kindness, particularly in helping younger members of his profession in their investigations, and dentists in all parts of the world owe a debt of gratitude to Mummery for his single hearted devotion to the art he loved so well.

The Mineral Springs of Pyrmont

ELSA DENHAM
New York

It is hard to determine just how far back in the dim past lie the origin and discovery of the springs of Pyrmont. Prehistoric graves, traces of old castles and forts, are mute witnesses of a community existing here centuries ago. Roman coins, oriental urns, hundreds of dress and belt buckles and a richly ornamented dipper were discovered some twelve feet under the ground in 1863 when excavations were started for the new foundations for the springs, evidence of offerings and donations to the deity of the healing waters. Roman history relates that after the battle of the Teutoburg Forest, the ill fated Roman general Varus retired his shattered legions to Pyrmont, where they remained to rest and regain strength through the partaking of the waters.

In every consequent century poets and writers have extolled the wonders of Pyrmont. An old chronicle relates that "in May of the year 1556, began the mysterious rush to the 'hilly springs,' " and ever since records testify to the "wondrous beauties of the resort and the properties of its waters."

Since earliest times Pyrmont has been the meeting place of royalty and one of its favorite resorts. The "Old Spring House," still in use today, was built in 1668 and the wonderful avenue of lindens leading from it was planted at the same time by order of the Duke Frederick of Waldeck-Pyrmont. Peter the Great of Russia, Frederick the Great, and Napoleon are numbered among the crowned heads who came to Pyrmont from year to year with their courts and retinues. The charming Queen Louise of Prussia, whose pathetic portrait looks down upon the visitor from the walls of the castle, was ordered to Pyrmont to recuperate after the death of one of her favorite sons. Celebrities from all over the world have foregathered at Pyrmont, with Benjamin Franklin as perhaps the best known among the earliest American patrons. The history of Pyrmont during the past centuries has been pictured in a series of contemporary or more modern paintings, on the walls of the new palatial Spring House.

The town is easily accessible. It lies on the main travel lines and American visitors arriving at Bremen, Hamburg or other continental ports can make excellent connections by fastest international trains.

The climate of Pyrmont is delightful. The air is clear and refreshing; there are no factories or smokestacks pouring forth gases and fumes. The large Teutoburg forest to the north and the hills surrounding Pyrmont stabilize the climate and exclude strong air currents.

Arriving at Pyrmont station one is immediately attracted by the picturesque red roofs showing among the green foliage. Crossing a small bridge, almost Japanese in style, over the winding Emmer, continuing along a row of delightful little villas nestling among well kept gardens, one suddenly stands in the centre of the village, in front of the ancient bubbling spring.

Few health resorts can boast of such complete and efficient health restoring establishments as are found at Pyrmont. Due to the "steel" drinking and bathing springs, naturally carbonated, its carbonated saline springs, its saline baths and extensive local moor deposits it has become a resort of first importance on the continent.

There are seven iron springs in use at Pyrmont which gush forth from a rift in the sandstone mountains above the spa. These various springs are respectively called the Main Spring or Steel Drinking Source, the Helenen Spring, the Bubbling Spring, the Friedrich Source, the *Augenbrunnen,* and two acidulous springs. The saline source springs, of slopes of the Bomberg down to the low lying valleys of the Emmer. The decomposed moor sod is rich in sulphuric acid and sulphuric salts and ammonia, humus acidity, etc., make it similar in composition to the moors of Franzensbad and Marienbad. Professor Kreussler of Bonn concludes his analysis of the Pyrmont moors saying: "It may be said with assurance that in those properties which are most characteristic and essential, and in which Franzensbad and Marienbad are recognized leaders, Pyrmont may, both in quantity and quality, safely enter into competition."

The drinking cures and the bathing cures are equally popular in Pyrmont. The principal spring,

Fig. 2.—Mineral spring fountain in enclosed promenade

which there are three, are the Salzbrunnen, the old saline source or weak saline, and the latest strong saline called *Bohrlochsole,* which flows from a driven depth of over 750 feet. The waters of the *Bohrlochsole* are piped directly to the old bathhouse, as well as to the new one, erected in 1906, and since then remodelled and improved and equipped with the most up to date medical appliances. It has been recently discovered that the three saline springs show an important degree of radioactivity.

The great specialty of Pyrmont is the combination of carbonic saline and iron water baths, according to given prescriptions and called steel saline baths. This form of cure, used particularly in heart complications, is growing in importance from year to year and its efficacy is increasingly becoming more widely recognized. Nauheim owes most of its reputation as a heart resort to just this form of baths and Pyrmont is gradually acquiring a similar repute.
